The activation energies were assumed to be similar to the energy of the bonds that were to be broken. The heats of formation of the free radicals were calculated as

166 kJ/mol (39.8 kcal/mol) for  $\text{H}_2\text{N}^\bullet$ , 144 kJ/mol (34.5 kcal/mol) for  $\text{H}_3\text{CNH}^\bullet$ , and 123 kJ/mol (29.5 kcal/mol) for  $(\text{H}_3\text{C})_2\text{N}^\bullet$ .

The very low-pressure pyrolysis of UDMH was reinvestigated [175]. The rate constant ( $k_{\text{uni}}$ ) for the first-order disappearance of UDMH in a static reactor has been determined under very low-pressure pyrolysis conditions [176]. The  $k_{\text{uni}}$  are not the rate constants of ultimate interest since they reflect the fact that energy transfer competes with chemical decomposition. The theory allows the determination of the high-pressure rate constants ( $k_a$ ) if the mode of decomposition is known. The heats of formation of the radicals  $\bullet\text{NH}_2$ ,  $\text{CH}_3\text{N}^\bullet\text{H}$ , and  $(\text{CH}_3)_2\text{N}^\bullet$  are known. These values should be usable for the prediction of the activation energy for N—N bond homolysis in the hydrazines. Measured rate constants for UDMH and tetramethylhydrazine bear this out but the rate constant for MMH did not.

The autodecomposition and auto-ignition temperatures of UDMH in inert gases (nitrogen, helium) or air were determined by squirting 0.1 mL into a 125-mL Pyrex round flask or 0.3 mL squirted into a 1-L Pyrex round flask [177]. In nitrogen or helium, UDMH autodecomposed above 666 K (740 °F). The addition of 40% diethylenetriamine (DETA) did not significantly increase the autodecomposition temperature threshold (671 K = 748 °F). This fuel mixture is also known under the code name U-DETA. In comparison to the auto-ignition tests in air conducted in the same apparatus, the autodecomposition of UDMH was difficult to observe since there was no flame and an audible report could be heard only at the very highest temperatures tested. The criterion used to determine whether a decomposition had taken place or not was the thermocouple reading from the gas space in the flask. The static conditions chosen for this test were intended to simulate the vapor space in a mostly empty propellant tank.

No explosive decomposition was encountered in the absence of air when UDMH vapor alone was heated to 873 K at 101 kPa or 777 K at 1.38 MPa (200 psig) [178].

Decomposition of UDMH in a quartz chamber heated to up to 1273 K preceding a time-of-flight mass spectrometer showed that significant decomposition occurred only above 800 K [179]. UDMH began to decompose at temperatures between 473 and 573 K (200 and 300 °C), as evidenced by the decrease in the parent peak of mass 60. The parent peak is no longer present at 1073 K (800 °C), indicating that complete decomposition had occurred.

Other investigators measured the UDMH thermal decomposition and found that UDMH rapidly decomposes at temperatures in the range of 673 to 773 K (400 to 500 °C). The half-life time of UDMH was 2.5 minutes at 693 K (420 °C) and 1.5 minutes at 733 K (460 °C).

A model analogous to a Frank-Kamenetskii equation was developed for UDMH droplet combustion in inert atmospheres [180]. Using this theory, an inverse-C-shaped curve relating the non-dimensional vaporization rate to the ambient temperature was obtained. Another approach was based on a steady-state theory and a simplified model. This produced an explicit expression for the ignition criterion.

### 1.3.1.2 Thermal Decomposition of UDMH in Shock Tubes

The thermal decomposition rate of UDMH vapor strongly diluted by different gases (Ar, O<sub>2</sub>, N<sub>2</sub>) was studied as a function of pressure (50–250 kPa) and temperature (900–1250 K) in a shock tube, and the UDMH concentration was followed by absorption spectrometry. The rate coefficient of UDMH decomposition at low concentrations was studied behind reflected shock waves [181]. The rate of disappearance of UDMH was measured by UV absorption spectrometry at 220 or 250 nm, depending on the concentration. Products of the reaction  $\text{UDMH} \rightarrow (\text{CH}_3)_2\text{N} + \text{NH}_2$  were extracted out of the shock tube into a time-of-flight mass spectrometer and identified by their  $m/e$  ratios. Initial pressures were 55–255 kPa and peak temperatures in the shocked material were 900–1250 K. In argon, the decomposition of UDMH followed the rate equation

$$k = (2.6 \pm 1.0)10^{12} \exp\left(\frac{-20960 \pm 540}{T}\right) \text{ s}^{-1}$$

where  $T$  is entered in kelvin. The Gulati data [181] agreed quite well with the earlier Just data. In nitrogen, the rate was almost identical, but in oxygen, the rate constant was quite different:

$$k = (5.6 \pm 3.5)10^{11} \exp\left(\frac{-18550 \pm 150}{T}\right) \text{ s}^{-1}$$

The activation energy in oxygen-containing UDMH mixtures is lower than in oxygen-free mixtures. It required more than 12 mol-% oxygen to make a noticeable difference to the half-life time of UDMH. Based on these results, it was concluded that the main mode of UDMH decomposition is the direct elimination of ammonia [182, 183]. The primary stage of UDMH decomposition was first order and its rate constant was only weakly dependent on the nature of the diluent. In the presence of oxygen, the half-life decomposition time of UDMH behind the reflected shock wave was very short ahead of the self-ignition delay. A simple relationship has been established between this delay, the shock parameters, and the concentrations of O<sub>2</sub>/UDMH/Ar mixtures. The global activation energy of the explosive reaction was of the order of 108 kJ/mol. This formula made it possible to estimate the delays in a wide range of composition, pressure, and temperature. A detonation can be initiated by a shock wave in O<sub>2</sub>/UDMH mixtures that are diluted or those that have not been mixed with argon. The detonation initiation conditions, the velocity, and the characteristic size of the detonation cells were determined. Correlations between the induction distance calculated in the detonation wave and the characteristic width of the cells on the sooted plate have been proposed

The ability of decomposing UDMH to affect the ignition delay of oxygen/hydrogen/nitrogen or oxygen/methane/argon mixtures in a shock tube is linked to the species (free radicals) present while UDMH is decomposing or reacting with oxygen. Ignition delays of lean, stoichiometric, and rich mixtures of hydrogen-air over a temperature range of 800–1400 K and a pressure of 2.5 atm were experimentally determined using a shock tube [184]. Small quantities of UDMH vapor were added

to these gas mixtures and their ignition delay periods for the same test temperatures and pressure as mentioned earlier were determined. Ignition was identified by the pressure rise as well as the visible light emission using piezoelectric pressure pick-ups and photomultipliers, respectively. The delay periods of lean, stoichiometric, and rich mixtures of hydrogen and air decreased with the addition of small quantities (less than 1%) of UDMH vapor. When the concentration of UDMH in the mixture exceeded 3%, the delay periods were longer than those obtained when no UDMH was present.

The effect of trace quantities (4 to 15% of methane) of pure UDMH on the ignition delay of oxygen/methane diluted with argon has been studied in relation to reflected shock waves over a temperature range of 1600–2100 K, at a pressure of 3 atm, and composition range of 0.5 to 2.0 ( $\phi$ ) times the stoichiometric ratio [185]. Ignition was identified by pressure rise and by visible light emission using piezoelectric pressure and photomultiplier detection, respectively. The delay periods were found to decrease with increasing quantities of UDMH. The reduction in the delay period was found to be more for  $\phi = 0.5$ , less for  $\phi = 1.0$ , and least for  $\phi = 2.0$ .

### 1.3.1.3 Decomposition of UDMH on the Surface of Single Crystals

Decomposing UDMH has been considered as an alternative to ammonia as a source of active nitrogen for the nitriding of semiconductors containing silicon, gallium, or indium.

The surface reaction of UDMH with Si(100) has been studied using temperature-programmed desorption spectroscopy (TPD), temperature-programmed static secondary ion MS (TPSSIMS), X-ray photoelectron spectroscopy (XPS), and Auger electron spectroscopy (AES) [186]. Adsorption of DMH on Si(100) at 170 K followed by annealing to 1100 K resulted in significant decomposition and went on to form surface carbide and nitride. TPD results showed that the only gas-phase desorption products were hydrogen and dimethylamine. XPS and TPSSIMS results indicated C–N bond cleavage beginning at 400 K, and by 600 K, all the C–N bonds dissociated.

The adsorption and decomposition of UDMH on Si(100) and the low-pressure nitridation of Si(100) using UDMH were investigated using XPS and TPD [187]. UDMH dissociatively adsorbed on Si(100) at 310 K with the cleavage of both N–N and N–H bonds. TPD and XPS showed that DMA desorption resulted in the complete removal of all the carbon on the surface by ~600 K.

The pyrolysis of UDMH, which was used as an alternative for ammonia in the MOVPE growth of nitrides on gallium or indium, was investigated in a horizontal reactor using quadrupole MS [188]. The thermal decomposition rate was investigated in relation to its dependence on reactor pressure, gas-flow rate, and sampling position over the susceptor. The temperature for 50% decomposition was 673–873 K (400–600 °C), which increased with lowering the pressure irrespective of the carrier gases. The pyrolysis rate was dependent on the pressure, and higher pressures induced a more efficient decomposition of UDMH.

### 1.3.2 Catalytic Decomposition of UDMH

The catalytic decomposition of UDMH is possible, however, it is not a practical mono-propellant since the large amount of soot it produces will clog all orifices [189–191]. Catalytic decomposition of UDMH has been evaluated as a method for disposing of unwanted surplus UDMH. Investigation into this area became necessary during demilitarization in the 1990s.

During the decomposition of UDMH on a Shell 405 catalyst in a quartz chamber, the HCN peak (mass 27) rose surprisingly over the entire temperature range studied rather than rising and then falling as previously found with MMH and  $\text{CH}_3\text{ONH}_2$  under the same experimental conditions [179]. The 17/16 ratio became less than one at approximately 673 K (400 °C). The mass 15 signal rose to a peak at a temperature of about 523 K (250 °C), then rapidly declined rather than remaining constant as previously found in the absence of a catalyst. In the catalyzed experiment, the HCN kept rising and was by far the prevalent degradation product in the UDMH catalytic decomposition. The anomalous behavior of the 17:16 ratio and the mass 15 peak could not be explained without further experimental data. It appears that the predominant reactions in the catalytic decomposition of UDMH are

Adsorption of UDMH on a high surface area catalyst carrier like alumina may precede its decomposition [192]. This adsorption may also be used for the removal of UDMH from contaminated air streams or in gas masks.

UDMH decomposition on an  $\text{Ir}/\text{Al}_2\text{O}_3$  catalyst at 373–473 K is a first-order process following two parallel paths; one leading to DMA and ammonia and the other leading to methane and nitrogen [193]. The decomposition of UDMH on a catalyst containing palladium supported on silica resulted in the formation of dimethylamine, ammonia, methane, and nitrogen [194].

The surface chemistry of UDMH decomposition on polycrystalline Pt has been investigated to determine the major reaction pathways followed by this asymmetric molecule [195]. Thermal dissociation plays an important role during and/or after adsorption at 100 K. Temperature-programmed desorption spectra showed the desorption of ammonia (340 K), hydrogen (320 and 430 K), hydrogen cyanide (490 and 610 K), cyanogen (780 K), and nitrogen (855 K). Auger spectra after heating to 1000 K indicated the accumulation of surface carbon. The proposed reaction path is initiated by some N–H bond dissociation at low temperatures (<180 K) to form  $(\text{CH}_3)_2\text{NNH}$  and H. This is followed by N–N bond breaking between 250 and 300 K, forming  $-\text{NH}_x$  ( $x \leq 2$ ) and  $-\text{N}(\text{CH}_3)_2$ . These species are then involved in a series of hydrogenation and dehydrogenation reactions that lead to the observed products.

Despite the dirty exhaust, the thermal decomposition of UDMH has been used in gas generators to drive propellant pumps in Russian rockets. The reaction was initiated with a solid propellant charge.

## 1.4 UDMH Flames in Oxidizing Atmospheres

### 1.4.1 Kinetics of Oxygen/UDMH Reactions

Based on kinetic results obtained using reflected shock waves in UDMH-dioxygen-argon mixtures, a two-stage reaction for UDMH oxidation in the gas phase has been proposed [196–198]. The first rapid reaction is the unimolecular decay of UDMH. The second step, which is slower and starts only after what seems like an inhibitory delay (induction period), is the reaction between the decay products and dioxygen. The ignition delay decreases with increasing  $O_2$  content of the mixture (assuming that total pressure and temperature are the same). Furthermore, the temperature dependence of the apparent activation energy also changes with increasing oxygen concentration. This points toward a very complex reaction mechanism, where the oxygen content affects the rate of more than one reaction step.

The combustion of UDMH vapor at 5.3 kPa (40 mm Hg) in oxygen was more readily initiated, propagated faster, and was sustained over a wider range of mixture ratios than the combustion of UDMH with nitrous oxide [199]. With oxygen, the maximum flame speed was 33.2 m/s at stoichiometric mixtures (20 vol.-% UDMH) and combustion was possible from five to 45% UDMH. The slowest flame speeds were 435 cm/s in mixtures with 5% UDMH and 540 cm/s in mixtures with 45% UDMH in oxygen. With nitrous oxide, the maximum flame speed was only 13.9 m/s and the minimum observed flame speed was 3.2 m/s at 28% UDMH.

### 1.4.2 Shock Tube Studies of Oxygen/UDMH Reactions

Mixtures of dioxygen and UDMH vapor heated rapidly in a shock tube underwent rapid decomposition followed by oxidation only after an ignition delay [183]. This confirms the observations already reported by [196–198] in the previous section. The ignition delays  $\tau$  of UDMH decomposition products were measured behind a reflected shock wave in a 38-mm-I.D. shock tube at 850–1550 K, 31–212 kPa, oxidizer : fuel mol ratios from 1 to 32.3, and argon diluent mol fractions from 0.69 to 0.95. For stoichiometric  $O_2$ /UDMH mixtures (mol ratio 4:1), the critical pressure/temperature conditions under which a self-sustaining detonation wave was initiated were 27.1 kPa/806 K and 45.7 kPa/736 K. The enthalpy of reaction of this reaction that leads to water vapor is  $-1974$  kJ/mol. The apparent activation energy of the reaction was 108 kJ/mol. Detonation velocities of ternary  $O_2$ /UDMH/Ar mixtures were measured both by pressure probes and by measuring the cell size on smoked witness tubes. Measured values

(~2000 m/s without argon dilution) were below predictions from CJ calculations for such mixtures.

At an initial pressure of 190 mm Hg, dioxygen/UDMH mixtures were easily detonated [200]. Dioxygen/UDMH vapor mixtures detonate more readily than dioxygen/methane or dioxygen/hydrogen mixtures.

Based on shock tube studies with reflected shock waves at 1600–2100 K, 303 kPa, and  $O_2$ /fuel equivalence ratios from 0.5 to 2.0, the addition of UDMH to  $O_2/H_2$  mixtures near the second limit of explosion decreased the ignition delay [197]. In contrast, the addition of UDMH to methane-oxygen-argon mixtures increased the ignition delay [185]. UDMH and its decomposition products scavenge some of the free radicals necessary for the chain initiation of the methane-oxygen reaction.

The fundamental gas-dynamic characteristics of the detonation, instantaneous combustion (explosion) in constant volume, combustion at constant pressure, and deflagration for hydrazine, MMH, UDMH, SDMH, or trimethylhydrazine in mixtures with oxygen or air that are diluted with argon at varied initial pressure and temperature values were examined [201, 202]. Spray detonation is also potentially relevant to the study of pulse detonation engines (PDEs) and other hypersonic propulsion systems exploiting detonative reactions. The main parameters of these processes were analyzed, both in relation to gaseous propellants and heterogeneous propellants, where the propellant is a highly dispersed, sprayed-aerosol cloud in an oxidant medium. Calculations were performed using the computer code SAFETY. Calculation results agreed with experimental data. For UDMH vapor, detonation wave velocity was predicted to be  $D_0 = 1701$  m/s. For a stoichiometric mixture of UDMH vapor with oxygen, the detonation wave velocity was predicted to be  $D_0 = 2432$  m/s. For a stoichiometric mixture of UDMH vapor with air, the detonation wave velocity was predicted to be  $D_0 = 1860$  m/s. A poorly dispersed spray of liquid UDMH aerosol in oxygen in a stoichiometric proportion to oxygen was predicted to detonate with  $D_0 = 1622$  m/s.

#### 1.4.3 Open-Air UDMH Burning in Open Pans

Open-air burning tests with UDMH in pans of 30 to 150 cm diameter in pools 8 cm deep showed that the linear burning rate of UDMH (despite its higher volatility) is less than that of hexane [200, 203]. This is because the UDMH flame is not a very radiant flame. Figure 64 in chapter “Hydrogen” of *Encyclopedia of Liquid Fuels* shows the pool burning rate of UDMH in comparison to the burning rate of other fuels. The linear burning rate of UDMH in a 1-m pool was 0.3 cm/min. The total thermal output of a UDMH fire was  $9.2 \text{ kJ cm}^{-2} \text{ min}^{-1}$ ,  $2.5 \text{ kJ cm}^{-2} \text{ min}^{-1}$  of which was radiated heat.

In 1-in. diameter burning pools of UDMH at atmospheric pressure, combustion could not be sustained if the oxygen concentrations of the surrounding air-nitrogen atmospheres were less than 14 volume percent [204]. Venting a liquid pool fire to a low-pressure environment tends to increase the liquid regression rate and the flame size. The liquid regression rate of a burning pool of liquid UDMH showed a very pro-

**Figure 15:** Liquid surface regression rate of UDMH burning in air in a 1-in. diameter tray as a function of surrounding pressure. (Reproduced and modified from [204].)

nounced increase in the liquid regression rate with decreasing surrounding pressure, as demonstrated in Figure 15.

It is relatively easy to extinguish Ae-50 fires with water [205]. In similar burning tests with UDMH, DETA, and fuel mixtures of the two mixed amine fuels (MAF-1 = 41% UDMH, 50% DETA, 9% acetonitrile, MAF-3 = 20% UDMH, 80% DETA), burning rates, radiation, and flame temperatures of open pan fires were measured in comparison to gasoline and methanol [206]. For blends with constituents of widely disparate boiling points, the initial burning rate was that of the more volatile component. Toward the end of a MAF burning test in a 122-cm tray, the burning rate approached that of DETA. The maximum temperature of a UDMH flame at the flame front was about 1370 K. Infrared measurements showed that UDMH vapor absorbs a higher percentage of its flame radiation than methanol, benzene, or hydrogen (of their respective flame radiations). This may contribute to energy transfer at the phase and flame boundary. The flash-over rates of a flame spreading over a pool of UDMH, MAF-1, or MAF-3 were about the same as that of gasoline. The burning rate of open UDMH fires was 0.31 cm/min compared to 0.8, 0.7, 0.6, and 0.13 for butane, hexane, benzene, and methanol, respectively [200]. Some of the UDMH burning tests were conducted in the open (quiescent) air in pans of up to 2.4 m (8 ft.) in diameter [207].

#### 1.4.4 Droplet Burning of UDMH in Oxidizing Atmospheres

The objective of an experimental study of single-droplet burning of UDMH in relatively quiescent atmospheres of both air and 100% oxygen in comparison to droplet

burning of hydrazine and RP-1 was to obtain information that would contribute to the establishment of burning rates, evaporation constants, and droplet lifetimes. This would thus provide an index for thrust chamber performance where more complex spray burning occurs [208]. The experimental method involved fuel drops suspended on a thin quartz fiber, with the variation of diameter with time recorded photographically. Data from the experimental study were plotted in terms of droplet diameter, and the droplet diameter squared versus time. Evaporation constants were calculated for each fuel and oxygen combination from these plots. A general conclusion drawn from this study was that a thrust chamber utilizing UDMH or  $\text{N}_2\text{H}_4$  with LOX could probably be constructed with smaller  $L^*$  and that it would be lighter in weight than LOX/RP-1 chambers (provided that all other conditions of atomization, mixing, etc., were the same).

The burning of UDMH droplets in oxidizing atmospheres (other than  $\text{NO}_2$ ) was studied to separate the monopropellant decomposition and oxidizer-supported flames of UDMH combustion, and to compare this to hydrazine and MMH [209–211]. The flat-flame burner could be fed with lean fuel mixtures, generating oxygen-rich hot gases in which secondary combustion of the droplet vapor decomposition products would take place. The conditions included 1660–2530 K at ambient pressure. The tests used single droplets suspended from a 100- $\mu\text{m}$ -diameter quartz filament and porous Alundum spheres. Droplet diameter could thus be varied from 0.11 to 1.91 cm. The fuel droplets were burned in the hot gaseous combustion products of a flat-flame burner to simulate rocket engine operating conditions. The flat-flame burner could be fed with lean fuel mixtures, generating oxygen-rich hot gases in which secondary combustion of the droplet vapor decomposition products would take place. The conditions included 1660–2530 K at ambient pressure. Decomposition flames were not luminous at all, but oxidation flames of all three fuels showed two separate distinct zones of luminosity

#### 1.4.5 Burning of Gelled UDMH

A model was developed for the burning of gelled UDMH droplets [212].

#### 1.4.6 Photolysis of UDMH

Photolysis by sunlight is an important mechanism (besides autoxidation and reaction with atmospheric ozone) for UDMH decay that has been accidentally released into the atmosphere [213]. The UV absorption spectrum of dimethylhydrazine has a continuum extending from 2800 Å to beyond 2000 Å. Despite the absence of structure, the continuum is probably experimental and indicates predissociation. The photolysis, using various light sources at several pressures and wavelengths, has been studied and the overall quantum yield was 0.3. The principal initial rupture of the molecule involves the scission of a hydrogen atom. Analytically, three molecules of the hydrazine give

one molecule each of  $\text{H}_2$ ,  $\text{N}_2$ ,  $\text{CH}_4$ ,  $\text{NH}_3$ ,  $\text{CH}_3\text{NH}_2$ , and  $(\text{CH}_3\text{N}=\text{CH}_2)_2$ . The low quantum yield was attributed to an additional reaction of dihydrogen to the free radical produced in the initial split.

The environmental fate of UDMH and the other hydrazines is determined by photolysis and autoxidation. Whereas kinetic and photolysis experiments are usually conducted with very low, and hence safe, partial pressures of UDMH, another way to study photolysis of UDMH is to operate at the brink of explosive vapor concentrations. Only minimal decomposition occurs in the vapor during the pre-irradiation period. However, the energy added by a flash of exactly-timed duration is sufficient to make the vapor explode. This mode of hydrazine, MMH, and UDMH decomposition was thoroughly investigated [214, 215]. The results were also compared to those obtained with ozone, which decomposes more readily than any of the hydrazines. For identical initial UV flash conditions, the half-life of UDMH was the shortest at  $48\mu\text{s}$  versus  $95\mu\text{s}$  for hydrazine and  $184\mu\text{s}$  for MMH.

#### 1.4.7 Radiolysis of UDMH

UDMH samples (100 mL UDMH) were irradiated with 8500000 rads of gamma rays. They generated 199 mL of radiolytic off-gas (measured at  $298\text{ K} = 25^\circ\text{C}$  and  $101\text{ kPa} = 1\text{ atm}$ ) [216, 217]. DETA, which is a component of the fuel mixture called Hydyne (consisting of 60 mass-% of UDMH and 40 mass-% of DETA), generated 101.2 mL of radiolytic off-gas. Assuming additive behavior, it was predicted that the off-gas of Hydyne would be 164.1 mL. When the samples contained 5 vol.-% of the free radical scavenger methyl methacrylate, the off-gas volumes were reduced by 18.2 and 11.0%, respectively. This prediction was confirmed in later radiolysis tests with Hydyne.

UDMH and (separately) hydrazine were radiolyzed at room temperature, exposing 1-g samples of liquid or 2-L samples of vapor to X-rays from an X-ray source operating with a tungsten target at 300 kV at intensities of 100 to 1000 roentgens per minute and total doses of  $4.1$  to  $2.3 \times 10^6$  rads [218]. The extent of decomposition was independent of dose rate and depended only on total dose absorbed. The decomposition products of UDMH were nitrogen, hydrogen, ammonia, methylamine, dimethylamine, hydrazine, and several unidentified products. Some of the products were low-volatility liquids that changed colors from blue to red to brown as they thawed in a cold trap. The G values (number of molecules decomposed per 100 eV of absorbed energy) for UDMH liquid were of the order of  $10^2$  and for UDMH vapor they were of the order of  $10^6$ , thus indicating a radical chain mechanism for decomposition. In the case of UDMH, decomposition reactions continued even after the radiation was turned off.

#### 1.4.8 Electron Impact Dissociation of UDMH

Electron impact dissociative ionization of UDMH and other methylhydrazines takes place in the inlet to most mass spectrometers. Electron impact dissociation also pro-

vides information about the bond strengths by looking at the fragments formed under those conditions. Smaller and smaller fragments are formed when the ionization chamber electrostatic potential is increased. Ionized fragments become visible in the mass spectrometer but uncharged fragments do not. Some of the work on electron impact fragmentation of methylhydrazines was already discussed in the section on MMH and, therefore, does not have to be repeated here.

The dissociation of methylated hydrazine ions was observed undergoing extensive fragmentation and rearrangement, leading to many fragments that had the same nominal mass but differed in chemical composition by an N versus  $\text{CH}_2$  moiety. Improved high-resolution quadrupole detection (0.005 amu) allowed one to distinguish ion fragments of the same nominal mass for MMH and UDMH [219]. The ratios of these close-lying fragment masses were measured for different electron impact energies and explained in terms of thermochemical thresholds and fragmentation mechanisms.

The 1,1-dimethylhydrazine ion  $(\text{CH}_3)_2\text{NNH}_2^+$  has two low-energy dissociation channels, the loss of a hydrogen atom to form the fragment ion  $m/e$  59,  $(\text{CH}_3)(\text{CH}_2)\text{NNH}_2^+$ , and the loss of a methyl radical to form the fragment ion  $m/e$  45, which is the methylhydrazyl cation,  $\text{CH}_3\text{NNH}_2^+$ . The dissociation of the 1,1-dimethylhydrazine ion has been investigated using threshold photoelectron-photoion coincidence spectroscopy in the photon energy range of 8.25–31 eV and using tandem MS [220]. Theoretical breakdown curves have been obtained from a variational transition state theory modeling of the two reaction channels and compared to those obtained from experiments. The 0 K enthalpies of formation for the two fragment ions  $m/e$  45 and  $m/e$  59 have been calculated from the 0 K activation energies obtained from the fitting procedure  $\Delta H_f^0[\text{CH}_3\text{NNH}_2^+] = 906 \pm 6 \text{ kJ/mol}$  and  $\Delta H_f^0[(\text{CH}_3)(\text{CH}_2)\text{NNH}_2^+] = 822 \pm 7 \text{ kJ/mol}$ .

#### 1.4.9 UDMH Decomposition by Neutron Beams

Sudden bursts of high-intensity neutron radiation may occur under atomic war conflict conditions, leading to rapid heating of fuels with the most efficient neutron absorption cross-section (usually hydrogen-rich fuels such as hydrazines or hydrocarbons). An analytical treatment of a cylindrical aluminum tank containing UDMH with varying ullage ratios showed that, for small ullages, the pressure rise is mostly due to the thermal expansion of the liquid, while for large ullages the increase in pressure is due to liquid evaporation and phase change [221]. Both the metallic casing and the liquid contents of a partially filled tank are subjected to heating that is uniform in time and space, although the liquid heats up at a different rate. Thermal expansion of the container walls is negligible in increasing the ullage volume. The heating due to absorption of radiation in the gas phase was neglected since its density is small in comparison to the density of the liquid. The increase in pressure is caused by two effects: **(1)** the differential expansion of the liquid and casing as the temperature increases and **(2)** the vaporization of liquid to maintain saturation vapor pressure with

an increase in temperature. Pressure increase was assumed to occur only as the result of thermal heating. Radiolysis of fuel in either the vapor or liquid phase was neglected, as was the solubility of pressurant gas in (or release of pressurant from) the propellant. Heating rates of the aluminum containers in an intense neutron beam were predicted to be so fast that the critical point of UDMH and the melting point of aluminum was reached within less than 15 s. UDMH was chosen as an example fluid but the effects of neutron beams on other hydrazine fuels would probably be similar.

#### 1.4.10 Reactions of UDMH

##### 1.4.10.1 Reactions of UDMH with Inorganic Compounds

The main interest in reactions with UDMH are those that might lead to its degradation as vapor in the atmosphere and reactions for the controlled destruction and decontamination of UDMH in wastewater from UDMH production and rocket tests sites. The chemical aspects of UDMH reactions are discussed here, and the application aspects will be discussed in later sections.

##### 1.4.10.2 Autoxidation of UDMH in the Air

For the study of the oxidation of liquid or dissolved UDMH by gaseous oxygen, the UDMH samples were first carefully freed from all contaminants that are commonly found in aged UDMH. All contaminants except FDMH could be removed by repeated refluxing and distilling over solid KOH. When reacting a fixed amount of oxygen in a closed vessel with UDMH in diethyl ether at 293 K (with some toluene added as an internal standard), the major products identified by GC were FDMH, methane, and nitrogen, and a trace of tetramethyl-2-tetrazene [222]. The solution did not change color at 293 K after 200 h but did do so after 24 h when kept at 298 or 303 K. In these solutions, tetramethyl-2-tetrazene, water, and *N*-nitroso-dimethylamine (NDMA, dimethylnitrosamine) could also be detected. Proton NMR of the residual liquid after evaporating the ether also revealed *sym*-hexahydro-1,4-dimethyltetrazine, the dimer of FDMH. Repeating the tests in cyclohexane instead of diethyl ether as a solvent led to similar results.

UDMH autoxidation proceeds faster in the light and metal containers (without light). Based on the results of early investigators, the autoxidation reaction was first-order in UDMH and zero-order in oxygen and was assumed to lead to formaldehyde-*N,N*-dimethylhydrazone, nitrogen, and water as the major products [223].

In another study of the gas-phase autoxidation of 1,1-dimethylhydrazine, ammonia, dimethylamine, NDMA, diazomethane, nitrous oxide, methane, carbon dioxide, and formaldehyde were detected in minor amounts [224]. The nitrous oxide yield increased if ammonia was added to the reacting mixture. Tetramethyl-2-tetrazene was not observed as a product of gas-phase oxidation of UDMH. The reaction was inhibited by

1,3-butadiene but accelerated by UV illumination. 1,1-Dimethylhydrazyl-2-hydroperoxide has been claimed as an intermediate but little proof was offered to support this hypothesis. Previous workers [225, 226] had claimed that vapor-phase oxidation of UDMH gave methyl azide but this has not been confirmed. It was later found that the IR absorption (a doublet at 4.72 and 4.78  $\mu\text{m}$ ) is due to diazomethane as an intermediate and short-lived product [224]. SDMH and trimethylhydrazine undergo rapid and complete autoxidation in the vapor phase at 298 K but tetramethylhydrazine does not react. Reaction products from SDMH autoxidation are azomethane and water. Trimethylhydrazine oxidizes to give formaldehyde *N,N*-dimethylhydrazone and water.

Preliminary investigative experiments on the UDMH-air reaction in a 20-L carboy or a 10-cm cell while monitoring the UDMH decay by recording the absorption at 908  $\text{cm}^{-1}$  revealed that the rate of oxidation is dependent on the surface : volume ratio [227]. Similar measurements had used a 44-cm short path cell and a 200-m long path cell (also with a 50-50 mixture of hydrazine and UDMH representing the Aerozine-50 propellant once used in the Titan launch vehicle) [228]. In the mixture, the hydrazines decayed (oxidized) more than ten times faster than the individual constituents by themselves. It was noted that UDMH by itself oxidizes ten times more slowly than either hydrazine or MMH under the same conditions. The data were too scattered to allow a statement on the oxidation kinetics. Additional Fourier transform infrared spectroscopy (FTIR) studies in a 60-L cell consisting of a 6-in. by 10-ft section of Pyrex pipe with an effective pathlength of 200 m revealed that the autoxidation of 6 ppm UDMH in 100% oxygen leads to FDMH as the only identifiable product [229–231].

It was difficult to study the autoxidation of hydrazines with air in Teflon-lined chambers because diffusion of UDMH vapors and the intrusion of ambient air oxygen, both through the Teflon foil, interfered with the autoxidation measurements [232]. The reaction was very slow in comparison to the other hydrazines. The half-life time of UDMH under these conditions was approximately 83.5 h.

It was shown that a 392-Pa (2.95-mm-Hg) low-pressure UDMH sample in an IR gas sample cell started to undergo pronounced changes within 49 h after the admission of air (94 kPa = 709 mm Hg) [233]. The weak combination band at 3160  $\text{cm}^{-1}$  completely disappeared and a new band formed at 3060  $\text{cm}^{-1}$ . The  $\text{CH}_3$  rocking band at 1032  $\text{cm}^{-1}$  decreased substantially and a strong new peak developed near 1010  $\text{cm}^{-1}$ . The strong  $\text{NH}_2$  rocking band at 908  $\text{cm}^{-1}$  nearly completely disappeared and a new peak formed near 885  $\text{cm}^{-1}$ . Further, the UDMH skeletal stretching band at 808  $\text{cm}^{-1}$  nearly completely disappeared and a new weak peak developed near 708  $\text{cm}^{-1}$ . Similar changes were observed in a second sample with an initial UDMH pressure of 4.2 kPa (31.9 mm Hg). The assignment of the new peaks to reaction products was not yet complete. Similarly, the UV spectrum of UDMH/dry air was scanned repeatedly for up to 73 h. A new absorption band formed at 235 nm while simultaneously UDMH absorption at 195 nm decreased. The peak at 235 nm was not NDMA (which was the main concern at the outset of this study), since NDMA absorbs at 227 nm. Instead, the spectrum of FDMH, when mixed with a fresh UDMH sample, closely resembled the spectrum of the

oxidized sample. A possible reaction would be

Kinetic analysis of the rate of UDMH disappearance indicated a first-order reaction with regard to UDMH. The half-life time under these conditions was 16 h. It has been proposed to study the progress of the reaction by MS instead of IR or UV absorption. MS would allow one to monitor the concentration of several species at the same time, even those which have no IR spectrum. Instead of constant-volume isothermal stirred reactors, shock tubes give information on kinetic rates by heating the reactants such as UDMH and oxygen very suddenly [196]. The kinetics of the oxygen/UDMH reaction were studied behind reflected shocks in a shock tube [198].

A simpler mechanism, although highly speculative and not yet supported by experimental data of its own, has been proposed [234]. This mechanism tried to account for the observed stoichiometry and changes in the order of reaction with time. It was assumed that the half-life time of UDMH in the air (or oxygen) is inversely proportional to the square root of its initial pressure. It was proposed that the initial step of the reaction is the formation (in the homogeneous gas phase) of the hydroperoxide  $(\text{CH}_3)_2\text{N}-\text{NH}-\text{OOH}$  and a free radical formed by abstracting a proton from the  $-\text{OOH}$  group. This intermediate could then bring about autocatalysis in the gas phase by chain branching. The fate of the hydroperoxide intermediate remains speculative but  $-\text{O}-\text{O}-$  splitting is likely and leads to  $\text{HO}^\bullet$  radicals forming. Similar peroxides (peracids) are formed in the autoxidation of aldehydes. Data for hydrazine and MMH autoxidation by this mechanism are not as reliable as those for UDMH. This may be caused by a greater sensitivity to surface effects in these two reactions. Difficulties in interpreting experimental results on the autoxidation of hydrazine or MMH may have been caused by the failure to recognize autocatalytic contribution by intermediates. The autoxidation of trimethylhydrazine leads to FDMH [235].

Ozone and  $\text{NO}_x$  are common atmospheric constituents and facilitate the oxidation of UDMH to nitrosamines [236]. Unoxidized UDMH was not mutagenic. However, oxidized samples suspected of containing NDMA were mutagenic [237]. In the case of *N*-aminopiperidine, both the unoxidized and the oxidized samples were mutagenic.

Earlier investigators had already hinted at the possibility of hydroperoxide intermediates in the autoxidation of UDMH. The toxicity of UDMH to bacteria may be caused by peroxide intermediates. Seven different recombinant bioluminescent strains of *escherichia coli* were used to describe the mechanism of toxicity of UDMH on bacteria, as well as to determine whether bacteria can sensitively detect the presence of this compound [238]. It was suggested that the action of UDMH on bacterial cells is determined by hydrogen peroxide, which may be formed in response to the reduction of the air oxygen level.

The autoxidation of UDMH in air is accelerated by illumination with light. The oxidation behavior of UDMH vapor was measured under different light conditions [239]. The results of GC-MS analysis showed that UDMH air oxidation produced a range

of products, including dimethylamine, partial hydrazone, *N*-nitroso dimethylamine, DMA acetonitrile, and acetaldehyde dimethyl hydrazone. With intense light, the rate of oxidation of UDMH accelerated. With the enhancement of light, oxidation products tetramethyl tetrazene, tetramethyl hydrazine, nitro dimethylamine, and dimethyl formamide were detected. In very bright light conditions, NDMA decreased significantly.

UDMH-containing wastes that were stored in contact with atmospheric oxygen contain a complicated mixture of UDMH degradation products. HPLC, high-resolution MS (HRMS), and NMR were used for the identification of highly polar and potentially toxic UDMH transformation products in this mixture [240]. Two series of triazole isomers with high ionization cross-section in electrospray ionization were isolated by repeated preparative HPLC. The structures of the isomers were established by tandem HRMS and NMR. The cytotoxicity of the isolated compounds is similar to that of UDMH or even higher.

#### 1.4.10.3 Catalytic Oxidation of UDMH

The oxidation of unwanted UDMH vapors in contaminated air can be accelerated by exposing the gas/vapor mixture to catalysts, preferably at elevated temperatures. Care must be taken to prevent flashbacks of the combustion into the feed system. Perovskites ( $\text{Ca}_{0.7}\text{Sr}_{0.3}\text{FeO}_{2.5}$  and  $\text{La}_{0.7}\text{Sr}_{0.3}\text{CoO}_{2.5}$ ) and supported spinels (20%  $\text{Cu}_x\text{Mg}_{1-x}\text{Cr}_2\text{O}_4/\gamma\text{-Al}_2\text{O}_3$ ) can be used as catalysts for this purpose at 423–973 K (150–700 °C) [241–244]. The catalyst  $\text{Cu}_x\text{Mg}_{1-x}\text{Cr}_2\text{O}_4/\gamma\text{-Al}_2\text{O}_3$  was found to be optimal regarding high yields of  $\text{CO}_2$  and low yields of  $\text{NO}_x$ .

The temperature dependence of the oxidation of UDMH on a Pt-containing catalyst was determined and the main intermediate and final reaction products were identified [245]. Platinum acted in the process as a multi-functional catalyst participating in dehydrogenation, hydrogenolysis, and oxidation. A new method was suggested for detecting UDMH in the air. This was based on the catalytic conversion of UDMH and the detection of the nitrogen dioxide formed with semiconductor gas sensors. The method was successfully used for detecting unsymmetrical dimethylhydrazine in the air at concentrations in the range of 0.1–10 mg/m<sup>3</sup>.

#### 1.4.10.4 Autoxidation of UDMH in the Anhydrous Liquid State

Oxygen was bubbled through pure UDMH and the vapors condensed in a cold trap at 195 K (–78 °C) [224]. Diazomethane was observed as an intermediate during UDMH autoxidation by sequential IR spectra (mainly during the initial phase of the process). If the autoxidation of UDMH was carried out in the presence of barium oxide, which would absorb water and presumably hydrogen peroxide also if any was formed, the diazomethane intermediate lifetime would be extended. So, it is possible that the diazomethane loss occurred by reaction with water that had formed as an autoxidation product, even in UDMH that initially was anhydrous. When the reaction was complete, the IR spectrum of the product closely resembled that of pure FDMH. The dark brown liquid left behind in the reaction vessel was mostly FDMH and NDMA.

#### 1.4.10.5 Autoxidation of UDMH in Solution

The autoxidation of UDMH by dissolved air in an aqueous solution is an important process if one has to determine the longevity of UDMH spills in clean surface waters without soil contact or suspended sediments. This information is needed for the design of wastewater treatment plants for wastewater drained from rocket test sites.

The rate of oxidation of UDMH (hydrazines spilled into surface water) was measured by pouring a measured amount of UDMH into 2 L of distilled air-saturated water in a glass flask and measuring pH and dissolved oxygen (D.O.) as a function of time [246]. The starting concentration of D.O. was typically above 7.5 ppm. UDMH at concentrations from 200 to 800 mg/L was studied to calculate the rate of oxidation. In some experiments, controlled amounts (0.125, 0.25, 0.5, 1.0 mg/L) of copper  $\text{Cu}^{2+}$  ion were added to test its effectiveness as a catalyst. In the sample containing the highest  $\text{Cu}^{2+}$  addition, D.O. dropped from 7 to 0.3 ppm in less than one minute. No effort was made to exclude ambient air during the experiment. However, since the experiments were short, reabsorption of oxygen from the air could be neglected. Besides, in free nature, additional oxygen from the air would also be available to aid the degradation of hydrazines in the water. The data detailing the rate of disappearance of oxygen and hydrazine were curve-fitted to a kinetic model with empirical constants of the type

$$\frac{d(DO)}{dt} = -\frac{k}{V}(DO)^n$$

where  $DO$  is D.O.,  $k/V$  is an average rate constant, and  $n$  is the average order of the reaction. Results for hydrazine, MMH, and UDMH are shown in Table 12.

**Table 12:** Autoxidation of hydrazines (in the absence of copper ions).

| Propellant      | Average order $n$ | Average rate constant, L/min |
|-----------------|-------------------|------------------------------|
| UDMH            | 0.540             | 1.6895                       |
| For comparison: |                   |                              |
| Hydrazine       | 0.985             | 4.0245                       |
| MMH             | 1.025             | 3.3296                       |

Data source: [246].

In a study of the rate of oxidation of UDMH as affected by pH and  $\text{Cu}^{2+}$  concentration, the authors concluded that for most real-life spill surface water conditions, UDMH would not persist for longer than a day or two in the absence of highly acidic conditions [247]. The kinetics of oxidation of MMH by D.O. in water has been measured at various acidities as a function of catalyst (cupric ion) concentration. In dilute solutions, the oxidation occurs through a cupric ion catalyzed process as well as by an uncatalyzed step.

Glassware used for an environmental degradation study of hydrazines in seawater, pond water, and pure water was carefully washed with 50% nitric acid before use. This rigorous cleaning was necessary to achieve reproducible results [248, 249]. Before the environmental degradation tests in soil were started, it was necessary to know the rate of degradation in surface waters without the effect of soil. In the absence of soil or catalysts, aqueous half-lives were 6–13 d for UDMH. Additional half-life data are summarized in Table 13.

**Table 13:** Half-life time of UDMH in natural waters.

| Fuel            | Initial concentration, mmol/L | Pond water, d  | Seawater, d    |
|-----------------|-------------------------------|----------------|----------------|
| UDMH            | 13.1                          | $22.2 \pm 6.9$ | $12.6 \pm 2.8$ |
| UDMH            | 6.5                           | $16.3 \pm 6.9$ | $12.6 \pm 1.1$ |
| UDMH            | 0.9                           | $7.3 \pm 1.0$  | —              |
| For comparison: |                               |                |                |
| MMH             | 19.0                          | $13.1 \pm 1.1$ | $13.1 \pm 2.2$ |
| MMH             | 9.5                           | $18.0 \pm 2.3$ | $24.1 \pm 8.8$ |
| Hydrazine       | 1.8                           | $8.3 \pm 0.6$  | —              |

Data source: [248,249].

For a wastewater aeration basin with a common hydraulic detention time of 9 h, the efficiency of organics removal was seriously hampered when the UDMH concentration exceeded 5 or 8 mg/L, respectively [250]. As far as organics removal is concerned, the “no effect level” would be approximately 2 mg UDMH/L. However, even at this low level, nitrogen speciation (ammonia conversion to nitrate) was severely impeded. Inhibition of nitrification occurred at concentrations above 0.5 mg MMH/L and above 1 mg/L for the other fuels. Some UDMH was still detectable under the same conditions and the efficiency of UDMH removal was only 96%.

The autoxidation of UDMH by D.O. in an aqueous solution (homogeneous single phase, no gas bubbling) led to FDMH and formaldehyde hydrazone, nitrogen, and water as its major products. When liquid UDMH without a solvent was reacted with bubbling oxygen, the following reaction products were found just as in the previous solvent studies: nitrogen, methane, FDMH, dimethyl nitrosamine, and tetramethyl-2-tetrazene [224]. Minor products were ammonia, dimethylamine, dimethylnitrosamine, diazomethane, nitrous oxide, methane, carbon dioxide, and formaldehyde. This reaction is of the first-order in UDMH and of zero-order in oxygen. It is catalyzed by metals and metal salts, inhibited by added 1,3-butadiene, and accelerated by UV light. A free-radical chain mechanism was postulated as the rate-determining reaction sequence. The 1,1-dimethylhydrazyl-2-hydroperoxide so formed was presumed to give the products FDMH, hydrazine, and hydrogen peroxide via a rapid sequence of wall reactions. Nitrogen and most minor products were

assumed to probably result from further wall reactions of hydrogen peroxide with UDMH, FDMH, and hydrazine.

The oxidation of UDMH was investigated using atmospheric oxygen in the air and dissolved hydrogen peroxide [251]. The reactions were carried out in the presence and absence of copper catalysis and at varying pH. Reactions were also carried out in the presence of hydrazine (a constituent) and with the UDMH of the rocket fuel Aerozine-50. In the presence of copper, UDMH was degraded by air passing through the solution. The efficiency of degradation increased as the pH increased but the carcinogen NDMA was formed at neutral and alkaline pH. Oxidation did not take place in the absence of copper. The production of NDMA occurred even at copper concentrations of  $< 1$  ppm. Oxidation of UDMH with hydrogen peroxide also gave rise to NDMA. When copper was absent, degradation of UDMH did not occur at acid pH. However, when copper was present, some degradation occurred at all pH levels investigated. The unwanted production of NDMA occurred mostly at neutral and alkaline pH. In general, higher concentrations of hydrogen peroxide and copper favored the production of NDMA. Dimethylamine, methanol, FDMH, formaldehyde hydrazone, and tetramethyltetrazene were also detected. The last three compounds were tested and found to be mutagenic.

The role of copper ions as a catalyst for UDMH oxidation can be explained by the oxidation of UDMH by copper(II) salts, thus forming dimethyldiazene as an intermediate [252]. The autoxidation reaction of UDMH proceeds via dimethyldiazene  $(\text{CH}_3)_2\text{N}^+=\text{N}^-$  as an intermediate [253]:

There were no gaseous reaction products. The reaction is first order with respect to each of the two reactants and was catalyzed by an alkali. The reaction constant is a function of the  $\text{OH}^-$  ion activity. At a pH of 12.89 and in the range of 288 to 308 K, the dependence of the reaction rate on the temperature would follow the Arrhenius equation

$$k = A \exp\left(\frac{-E}{RT}\right)$$

where  $A = 4.42 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1}$  and  $E = 58.9 \text{ kcal/mol}$ .

The toxicity of UDMH to bacteria may be caused by peroxide intermediates [238]. The oxidation of aqueous solutions of UDMH in the presence of Cu-, Fe-, Co-, and Mn-containing catalysts of the hydroxide type supported on oxide carriers are potentially useful for the detoxification of UDMH rinse waters [254]. The Cu-containing samples proved to be the most active. The dependence of the reaction rate on the pH value, temperature, and the ratio of the catalyst sample to the solution volume was investigated in trying to achieve optimum conversion. The main products of the reaction were hydrazones and formazane. The reaction was shown to occur via different mechanisms in neutral or alkaline solutions.

Another study on the autoxidation of UDMH solutions and degradation of UDMH in the environment attempted to identify the reaction mechanism with and without the addition of a copper(II) sulfate catalyst which was dependent on pH, UDMH, or  $\text{Cu}^{2+}$  concentrations [255]. UV scanning spectroscopy demonstrated the familiar spectrum of tetramethyltetrazene with maxima at 326 and 236 nm in a pH 9.12 buffer. Acidification shifted the first maximum reversibly to 356 nm. Next, oxidation was studied by proton magnetic resonance (PMR) in  $\text{D}_2\text{O}$  as a solvent. Again, the spectrum was different for the basic and acidified condition. However, due to a lack of pure reference compounds, neither spectrum could be assigned. Most likely, the NMR spectra were those of multi-component mixtures, including unreacted UDMH. The bromination of UDMH was studied as a possible route to singly, better-defined oxidation products but with little success. The initial oxidation product of UDMH appears to be the short-lived 1,1-dimethyldiazene, which may dimerize to tetramethyltetrazene or become oxidized further. When measuring the concentration of  $\text{O}_2$  with a D.O. meter as a function of time, pseudo-first-order reaction rate constants were obtained. The data indicated that the free-base form of UDMH undergoes a reaction and that copper catalysis is not significant at concentrations less than  $10^{-6} M$  in UDMH.

Continuing the study of autoxidation kinetics of UDMH solutions, aeration of  $1 \times 10^{-4} M$  UDMH solutions in the presence of  $\text{CuSO}_4$  led to formaldehyde and 1,5,5-trimethylformazan. Aeration of more concentrated solutions ( $3\text{--}5 \times 10^{-3} M$ ) led to the formation of tetramethyltetrazene [247]. In dilute solutions, the oxidation occurred through a cupric ion catalyzed process as well as by an uncatalyzed step. The extent of the formation of NDMA depends upon the initial UDMH concentration. In dilute solutions, NDMA was not formed, but in more concentrated solutions, NDMA formation increased with increasing UDMH content; it reached a maximum at 60–80% UDMH (by volume) in water and then decreased. The NDMA yield appeared to approximately parallel the viscosity of the medium, and it was speculated that the factors which control viscosity may also be responsible for governing NDMA formation.

NDMA was not found in the dilute solution experiments within the accuracy of the detection method ( $10^{-5} M$ ). This contradicts findings reported earlier by other investigators [224]. However, when more concentrated UDMH solutions (10–90 vol.-%) were allowed to stand in contact with air, NDMA was formed to a significant extent, especially in the range of 60 to 80 vol.-% UDMH in water, and reached a maximum within 5 d. Peroxides may form in aged UDMH solutions as intermediates. It was recommended to keep UDMH dry to minimize the rate of NDMA formation during storage.

The influences of concentration of oxygen and contact with metallic materials on the rate of oxidation of UDMH during autoxidation processes were studied using GC and MS [256]. Stainless steel and aluminum can accelerate the autoxidation of UDMH and increase the concentration of DMA as an intermediate autoxidation product. Increasing the concentration of oxygen can increase the rate of oxidation of UDMH and the concentration of DMA immediately.

To explore the degradation mechanism of UDMH under conditions of actual storage, liquid-phase reaction products of the gas-liquid two-phase reaction of UDMH with  $O_2$  and air, and the change in the content of main gaseous products with time, under four sets of conditions of oxygen, oxygen/water, air, and air/water, were determined by GC-MS, and their reaction mechanisms were analyzed [257]. The results showed that there are 19 different autoxidation products of UDMH, of which NDMA, FDMH, dimethylamine, water, and *N,N*-dimethylformamide were the main products. Moreover, there were four newly-detected products: *N,N,N',N'*-tetramethylmethylenediamine, 4-methyl urazole, tris(dimethylamino)methane, and *N,N*-dimethylurea. The oxygen and oxidation of UDMH in the gas phase greatly enhances the generation of NDMA. Thirty-per-cent of the degraded UDMH was converted to NDMA and the mass fraction of NDMA in the gas phase was up to 1.3%, whereas the generation rate of NDMA in the reaction with air was about 5%.

In a UDMH autoxidation experiment, the air-flow from an air compressor was first passed through an air filter. This was then successively passed through a concentrated  $H_2SO_4$  gas-washing flask and a solid NaOH neutralizer to remove  $CO_2$ , then passed through  $CaCl_2$  drying agent. Finally, it was bubbled into the liquid UDMH sample [258]. The sample size was 700 mL and the air-flow rate was 15–25 mL/min. The exhaust air was bubbled into diluted  $KMnO_4$  solution to oxidize UDMH vapor completely before releasing the air to the atmosphere. UDMH samples, with and without a metal oxide catalyst, were oxidized by dry air for 10 h then oxidized in static air for 14 h. The samples turned yellow during the test and were then analyzed by GC/MS.

UDMH is a reducing agent and hydrogen peroxide is usually considered an oxidizing agent. Unusually, that hydrogen peroxide was detected as an intermediate and by-product of UDMH autoxidation in aqueous solutions at very small UDMH concentrations [259].

#### 1.4.10.6 Reactions of UDMH with Hydrogen Peroxide in Solution

Hydrogen peroxide is being used for wastewater treatment in many industrial applications. Therefore, it would be logical to test it as a means of destroying unwanted UDMH in solution as well.

It is unlikely that anyone would want to react anhydrous UDMH with high-concentration (>70%) High Test Hydrogen Peroxide (HTP), because it is, after all, commonly known that this would lead to a hypergolic reaction and this belongs in a future *Encyclopedia of Hypergolic Bipropellant Combinations*. Therefore, if one only wants to safely destroy surplus UDMH in solution, sufficient dilution of both liquids with water is required to slow down the reaction.

It has been suggested that  $H_2O_2$  may actually be an intermediate product in the autoxidation of UDMH in solution so this is another reason to look at reactions between UDMH and  $H_2O_2$ . The use of high-resolution MS for the study of the reaction products of UDMH oxidation with hydrogen peroxide in an aqueous solution enabled the detection of hundreds of nitrogen-containing products of the CHN and CHNO types

that are formed via radical processes [260]. The vast majority of the compounds had not been previously considered as possible products of the transformation of rocket fuel. It was shown that the oxidation of UDMH proceeds in two stages with the formation of a great number of complex unstable intermediates that contain up to ten nitrogen atoms. These intermediates are subsequently converted into final reaction products with a concomitant decrease in the average molecular weight. The intermediates and final products of the oxidative transformation of UDMH were characterized based on their elemental composition. Possible compounds matching the mass-to-charge ratio ( $m/e$ ) of the most intense peaks in the mass spectra were proposed. There were indications of the presence of the following classes of heterocyclic nitrogen-containing compounds among the oxidation products: imines, piperidines, pyrrolidines, dihydropyrazoles, dihydroimidazoles, triazoles, aminotriazines, and tetrazines. The results obtained open up possibilities for the targeted search and identification of new toxic products of the degradation of UDMH and, as a result, a more adequate assessment of the ecological impact of rocket propellant spills.

A UDMH destruction method using  $\text{H}_2\text{O}_2/\text{CuSO}_4$  leads to ca. 25% NDMA, which is a toxic and unwanted end product [261]. The amount of UDMH destroyed is affected by the order of the addition of  $\text{H}_2\text{O}_2$  and  $\text{CuSO}_4$ . When the  $\text{CuSO}_4$  is added first, only ca. 65% of the UDMH is destroyed, while the reverse order of addition leads to 100% destruction of UDMH.

Fenton's reagent, a mixture of hydrogen peroxide and iron(II) salt solutions, is a known powerful oxidizer containing hydroxyl free radicals.

The free radicals generated by this process then engage in secondary reactions. For example, hydroxyl is a powerful and non-selective oxidant. Oxidation of organic compounds by Fenton's reagent is rapid and exothermic and results in the oxidation ("mineralization") of contaminants to primarily carbon dioxide and water. Fenton's reagent can be used to destroy organic compounds like UDMH. The iron ions can be either in solution or in suspension in heterogeneous systems. The iron ion can be embedded in a zeolite for maximum surface area of a heterogeneous catalyst. This is a good way to detoxify wastewaters containing UDMH. There are several more references to this process in Section 1.6.6.2.

The zeolite FeZSM-5 is active as a catalyst in the oxidation of UDMH in aqueous solutions using hydrogen peroxide [262]. The performances of heterogeneous and homogeneous Fenton systems were compared, and complete UDMH mineralization (conversion to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ ) was achieved. Formic and acetic acids, as well as nitromethane, were identified as oxidation by-products. Adsorption properties of FeZSM-5 with respect to hydrogen peroxide, UDMH, and NDMA, and the effects of the oxidant and

UDMH concentrations, temperature, and the pH of the aqueous solution have been studied.

Iron-containing zeolites can be activated by pre-treatment with mineral and carboxylic acids to become more active in heterogeneous Fenton reactions such as the destruction of UDMH with hydrogen peroxide [263].

UV spectroscopy was used to trace and analyze the oxidative degradation products of UDMH in wastewater under the influence of two oxidation systems:  $\text{Cu}^{2+}/\text{H}_2\text{O}_2$  and  $\text{Fe}^{2+}/\text{H}_2\text{O}_2$  Fenton system [264]. The degradation products of two oxidation systems, the  $\text{Cu}^{2+}/\text{H}_2\text{O}_2$  system and the Fenton system, were analyzed. The UV peaks of UDMH and unsymmetrical dimethylhydrazone (FDMH) were at 200 and 235 nm, respectively. The two systems could effectively decontaminate UDMH wastewater, but  $\text{Cu}^{2+}/\text{H}_2\text{O}_2$  had more intermediate products and higher toxicity. The addition of  $\text{H}_2\text{O}_2$  before adding  $\text{Cu}^{2+}$  can reduce intermediates. The addition of iron powder in addition to  $\text{Fe}^{2+}$  was beneficial in decreasing toxic intermediates.

#### 1.4.10.7 Reactions of UDMH with Carbon Dioxide

Salts formed between UDMH and carbon dioxide and their corrosion products (in contact with metals) are not totally soluble in UDMH and may precipitate and clog orifices and filter screens. Similar to the formation of carbazic acid in hydrazine, the reaction of UDMH with carbon dioxide may form salts of 2,2-dimethylcarbazic acid:

This salt has been isolated, and it was noted that it sublimates at 330 K (57 °C) and thus cannot be separated from UDMH by simple distillation [265].

The stability of UDMH is greatly affected by the presence of impurities. Six new metal complexes that are likely corrosion products containing 1,1-dimethylhydrazinecarboxylate and methylhydrazinecarboxylate were prepared. The effects of these complexes on the homogeneous decomposition rates of the propellants were investigated. The Ni(II) 1,1-dimethylhydrazinecarboxylate complex has a greater effect than the Mn(II) complex on the stability of UDMH [266].

#### 1.4.10.8 Reactions of UDMH with Nitrogen Dioxide

The hypergolic reaction of UDMH with dinitrogen tetroxide (NTO) is the main reason that much UDMH has been produced and consumed over the past 70 years. The reaction between the two liquids is hypergolic. The application of the NTO/UDMH propellant combination in rocket engines will be discussed in a future *Encyclopedia of Hypergolic Bipropellant Combinations*, in the chapter titled “Hypergolic Combinations With Nitrogen Oxides.”

Slow and flameless reactions of UDMH with  $\text{NO}_2$  in the gas phase might occur in the vicinity of propellant storage areas where propellant has leaked, or in a rocket combustion chamber after the engine has shut down and the dribble volume slowly has emptied itself without a combustion reaction. These reactions also must be antic-

ipated if an NTO/UDMH bipropellant engine is fired for an extremely short pulse and fails to ignite.

The gas-phase reaction of UDMH with  $\text{NO}_2$  at low partial pressures was shown to produce NDMA, dimethylamine, dimethylhydrazinium nitrate, methanol, *N,N*-dimethylformamide, water, nitric oxide  $\text{NO}$ , nitrous oxide  $\text{N}_2\text{O}$ , nitrogen, and carbon dioxide [267–270]. *N,N*-Dimethylformamide was observed in significant amounts because it is not susceptible to further attacks from  $\text{N}_2\text{O}_4$ . The reaction products of the three hydrazines with NTO were analyzed by using mass spectrometry, GC, and IR spectrophotometry. Some of the GC fractograms showed as many as eight peaks, some of which still have not yet been identified.

In a study using a  $2.4 \times 2.4 \times 1.2$ -m Teflon foil-lined chamber at atmospheric pressure, concentration-time plots for reactants ( $\text{NO}_2$  and UDMH), intermediates, and products could be measured using *in-situ* FTIR spectroscopy with multiple paths of the beam running through the chamber [271, 272]. Experiments were conducted in air and nitrogen atmospheres in 3800-L and 6400-L Teflon reaction chambers. Reactant and product concentrations were measured by long pathlength (68.3–102.4 m) FTIR spectroscopy. The reaction occurred with an apparent overall reaction rate (defined in terms of UDMH decay) of  $(2.3 \pm 0.2) \times 10^{-17} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . The major products were nitrous acid and tetramethyltetrazene-2, according to

regardless of the initial reactant concentration or whether the reaction was carried out in nitrogen or air. There was no observable reaction of  $\text{NO}$  with UDMH in nitrogen. However, if  $\text{NO}_2$  was injected,  $\text{NO}$  would also participate. One of the unidentified intermediate reaction products was thought to be a nitrosohydrazine  $(\text{H}_3\text{C})_2\text{NNHNO}$ , which might undergo unimolecular decomposition to  $\text{N}_2\text{O}$  and dimethylamine.

NTO/UDMH is the propellant combination used by the Russian Zvezda propulsion module on the International Space Station. The Zvezda engine has to be fired periodically to maintain the space station orbit and to prevent it from falling down. There is concern that UDMH nitrate may sublime and condense on the shadow side of the station on optical surfaces or solar panels. Astronauts conducting EVA work may come into contact with the sublimate and bring it back with them into the airlock when they return. It is necessary to have detection and mitigation methods for the products of incomplete combustion. In addition to UDMH nitrate, methylammonium nitrate and dimethylammonium nitrite (which are all non-combustion reaction products of UDMH and NTO) can contaminate spacesuits during EVA operations. They can react with water on return to the International Space Station airlock to form NDMA, which is a carcinogen. Detection methods for assessing nitrite and DMA contamination were investigated [273, 274]. The methods were based on color-forming reactions in which the intensity of the color is proportional to concentration. A concept color detection kit using a commercially available criminal investigation field test for methamphetamine coupled with nitrite test strips was developed and used to detect DMA and nitrite.

In the case of launch failures of launch vehicles using storable propellants, large amounts of  $\text{N}_2\text{O}_4$  and UDMH or Aerozine-50 are released into the atmosphere. Under these conditions, only partial combustion and incomplete  $\text{NO}_2$ -UDMH reactions occur at the interphase of the oxidizer-rich and fuel-rich clouds with incomplete mixing. This depends on the catastrophic situation and the atmospheric conditions at the accident site. A large number of toxic compounds can be formed under those conditions [275].

Products of the reaction of UDMH with nitrogen dioxide in aqueous solutions were characterized by high-resolution MS with electrospray ionization [276]. It was found that more than 200 different CHO, CHN, and CHNO compounds were formed in the reaction. The main component was NDMA. Among the many products of the transformation of UDMH, *N*-nitrosodibutylamine was identified for the first time. These compounds can be found in surface and ground waters at the places of the impact of spent rocket stages containing both UDMH and NTO.

#### 1.4.10.9 Reactions of UDMH with Ozone and/or Atomic Oxygen

The reactions of UDMH with ozone are of interest for several reasons. One is the environmental fate of UDMH if it is accidentally released in the upper atmosphere where there is a prevalence of atomic oxygen. The other is the controlled use of ozone for the decontamination of wastewater from UDMH production and rocket test installations.

If UDMH is released in the upper atmosphere where it is exposed to direct incidence of sunlight, it is expected to react with ozone, atomic oxygen, and hydroxyl radicals. The reaction of atomic oxygen with UDMH may excite fluorescent emissions at characteristic wavelengths in the UV and visible range. In trying to explain high-altitude plume signature phenomena, near-UV, and visible emissions resulting from the reaction of high velocity (7 to 12 km/s)  $\text{O}^+$  ions and  $\cdot\text{O}$  atoms with UDMH were measured using a pulsed fast O-atom source [277]. The background-corrected spectrum consisted of four major bands assigned as OH(A,  $\Delta v = 0$ ), NH(A-X), CH(B-X), CN(B-X), and CH(A-X). No other major features could be seen over the range of 250–650 nm. A broad continuum extending from 350 to 750 nm, which peaked near 525 nm, was also observed. Experiments varying the  $\text{O}^+$  concentration revealed that the intensity of all of the band emissions (except OH(A)) was proportional to the square of the  $\text{O}^+$  concentration. This implied that the emissions arose primarily from ion-molecule reactions with  $\text{O}^+$  through a two-step mechanism.

Rate constants for the reactions of atomic oxygen with hydrazine, MMH, or UDMH have already been detailed in the chapter “Methylhydrazine” (within the section on MMH reactions) [278, 279].

The gas-phase kinetics of  $\text{O}(^3\text{P})$  and OH reactions with  $\text{N}_2\text{H}_4$ ,  $\text{CH}_3\text{NNH}_2$ , or  $(\text{CH}_3)_2\text{NNH}_2$  were studied in a discharge flow-tube apparatus [280, 281]. The reactions were studied in 267 Pa (2 mm Hg) of He dilution under pseudo-first-order conditions in the transient species concentration, with a known excess of hydrazines concentration. The steady-state concentration temporal profiles of the transient

species were directly monitored by fluorescence techniques to deduce the absolute second-order reaction rate coefficients. The Arrhenius expression

$$(1.96 \pm 0.29) \times 10^{-11} \exp(20 \pm 40)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

in the temperature range of 252–640 K was obtained for the reaction of  $\text{O}(^3\text{P})$  with  $(\text{CH}_3)_2\text{NNH}_2$ . The corresponding expression

$$(2.00 \pm 0.30) \times 10^{-11} \exp(330 \pm 80)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

in the range of 232 to 374 K was determined for the  $^{\bullet}\text{OH}$  reaction. Alkylation in the hydrazine molecule allows direct H-abstraction mechanisms to operate in these reaction systems. A later study [282, 283] using direct laser-induced fluorescence monitoring of the  $[\text{OH}]$  temporal profiles in a known excess of UDMH yielded the following absolute second-order OH rate coefficient expression:

$$k_1 = (3.35 \pm 0.60) \times 10^{-11} \exp(175 \pm 25)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1},$$

for reactions with UDMH in the temperature range 232–637 K.

The gas-phase reaction kinetics of O atoms with UDMH was studied in a discharge flow-tube apparatus under pseudo-first-order conditions in  $[\text{O atom}]$  concentrations [282, 283]. Direct VUV CW-resonance fluorescence monitoring of the  $[\text{O atom}]$  concentration temporal profiles in a known excess of UDMH yielded the following absolute second-order O-atom rate coefficient expression in the temperature range of 232–644 K and in He pressure of 2.0 Torr:

$$K_1 = (1.94 \pm 0.34) \times 10^{-11} \exp(25 \pm 25)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

The oxidation of UDMH in aqueous solution by gaseous (dissolved) ozone was characterized by the temporary appearance of red and orange colors, which was attributed to an intermediate diazolike compound [284–286] formed in the reaction

No oxidation by ozone was detected in acidic solutions. In neutral and weakly alkaline medium, analysis of gas products and the UV analysis of the liquid product suggested that the following reaction takes place:

Under the same conditions, using pure oxygen instead of ozone, produced only a complex mixture of organic compounds. If ozone or ozone-oxygen mixtures reacted directly with liquid UDMH instead of adsorbed or dissolved UDMH, up to nine products of partial oxidation were isolated and identified. However, the reaction never proceeded all the way to carbon dioxide as intended [287]. NDMA was the most stable and persistent intermediate. Other oxidation products were dimethylamine, dimethylformamide (DMF), tetramethyltetrazene, SDMH, and FDMH. Increasing the temperature from 293 to 323 K increased the rate of NDMA formation by a factor of six

but did not alter the product composition appreciably. When UDMH was adsorbed on alumina and then reacted with ozone, the colored intermediate presumed to be  $(\text{CH}_3)_2\text{N}=\text{N}$  was observed again. Half of the UDMH was oxidized to small fragments and the other half was converted to tetramethyltetrazene [288, 289]. It was suggested that the first stage of the oxidation of adsorbed UDMH is the dissociation of N—H bonds, leading to the formation of water. This is followed by the splitting of C—N bonds. The intermediate compounds can be stabilized by adsorption on alumina so that they can be studied by their IR spectra [290, 291]. The ozonization of all three hydrazines was studied in a gas bubbling column containing 30 L of solution. For runs when an ozone concentration of 13 mg/L air or less (approximately 1% by volume ozone in air) was desired, the ozonator feed gas was air. Although UDMH was reduced to approximately its detection limit after 35 minutes, 68% of the initial total organic carbon (TOC) and 40% of the initial chemical oxygen demand (COD) remained in the solution. Some of this residual organic material was determined to be methanol. Two peaks in the mass spectrum of low-concentration UDMH ozonation products were identified as NDMA and DMF. At higher UDMH concentrations, more than 15 peaks were detected and several remained unidentified. Two of the identifiable peaks were formaldehyde methylhydrazine,  $\text{CH}_3\text{NHN}=\text{CH}_2$ , and FDMH,  $(\text{CH}_3)_2\text{N}-\text{N}=\text{CH}_2$ .

Theoretical quantum mechanical calculations, used to study the reaction mechanism of UDMH with oxygen (O) atoms, predicted rate constants of the O-atom reactions with UDMH over a wide temperature range of 200–2000 K [292]. This reaction is likely to occur if UDMH diffuses to the ozone layer in the stratosphere, although it would most likely decompose before it gets there. The agreement between the theoretical predicted and experimental measured rate constants was good around room temperature. The channels of H abstraction from the  $-\text{NH}_2$  position favor temperatures below 1200 K. With increasing temperature, contributions from other channels must be considered. The reactivity of  $\text{N}_2\text{H}_4$ , MMH, and UDMH toward atomic O was compared to explore the methylation effect on hydrogen abstraction.

The formation mechanisms of NDMA from MMH, UDMH, or hydrazones during ozonation, which typically forms high NDMA conversion yields (60–90%), were investigated by using DFT computational methods [293]. Intermediates of the reactions included 1-formyl-2,2-dimethylhydrazine, FDMH, and acetone dimethylhydrazine. A new NDMA formation mechanism from hydrazines during ozonation was proposed, in which the initial step is hydrogen abstraction rather than the previously reported oxygen addition. For hydrazones, the C atom of the  $-\text{N}=\text{C}-$  moiety in hydrazones is the preferred point of attack by ozone to generate *N,N*-dimethylaminonitrene, which is an important intermediate in NDMA formation during ozonation. The reactivity order of the H atoms in hydrogen/hydride ion abstraction by ozone is  $-\text{NH}_2 > -\text{N}(\text{CH}_3)_2 > -\text{CO}-\text{NH} \sim =\text{C}(\text{CH}_3)_2 > =\text{CH}-$ . Formation pathways of some experimentally detected compounds, i.e.,  $\text{HOOH}$ ,  $\text{HOOH}$ , and  $\text{HCOH}$ , in the ozonation of hydrazines were examined.

#### 1.4.10.10 Reactions of UDMH with Sulfur Dioxide

There is not much sulfur dioxide in polluted atmospheres to make reactions with SO<sub>2</sub> contribute to UDMH degradation in air. The reaction of sulfur dioxide with UDMH in trichloromethane produced 2,2-dimethylhydrazinium 2,2-dimethylhydrazinesulfate, a low-melting and readily subliming (300 K) salt [294]. Similar salts were obtained from 2-hydroxyethylhydrazine and phenylhydrazine. There do not seem to be any practical applications for such salts, so why patent them?

#### 1.4.10.11 Reactions of UDMH with Halogens and Hypochlorite

Hypochlorites in the form of chlorine bleach (sodium hypochlorite) or calcium hypochlorite (HTH) are frequently used for the disposal and destruction of hydrazine N<sub>2</sub>H<sub>4</sub>. In the case of hydrazine, N<sub>2</sub>H<sub>4</sub>, there would be no concern about by-products (except maybe HN<sub>3</sub>). In the case of methylhydrazines, the reaction does not always go to completion and undesirable toxic intermediates may linger around, even after the hypochlorite reaction has ceased. The oxidative destruction of unsymmetrical dimethylhydrazine (UDMH) by a molar excess of Ca(OCl)<sub>2</sub> leads mainly to FDMH and tetramethyl tetrazene but not to NDMA [261].

In the earlier experiments with UDMH and hypochlorite, GC/MS and GC/FTIR analysis of the reaction mixture revealed 90–100 different compounds [295–298]. The major reaction products were formaldehyde *N,N*-dimethylhydrazone (identified from its IR and its mass spectrum) and NDMA. Other confirmed reaction products were *N,N*-dimethyl cyanogen (relatively minor), DMF (relatively minor), and chloroform (minor). Neutralization of an acidic solution yielded many new peaks, multiply chlorinated, and all unidentifiable. No nitrosamines were found in the acidic run. In trying to explain the kinetics of this process, 1,1-dimethyl-2-chlorohydrazine may be the first product of the attack of hypochlorite on UDMH. In the next step, it is believed to lose HCl to form a reactive diazene intermediate

In an aqueous solution, the following equilibrium is also present:

During the course of the neutralization of UDMH with hypochlorite, the reaction mixture became yellow, then orange, and then red-brown. The dark red-brown color faded with further addition of hypochlorite, although gas continued to evolve. The extraction with dichloromethane yielded a yellow aqueous-phase and a dark yellow or orange organic layer. Back extraction with water also formed a yellow water layer. Hypochlorite oxidation products of UDMH were FDMH, chloroform, carbon tetrachloride, acetaldehyde ethylidene hydrazone, *N,N*-dimethylformamide, dimethylnitrosoamine, dimethyl cyanamide, 5-methyl-2,4-dihydropyrazol-3-one, isoxazolidine, and 1-methyl-1,2,4-triazole. Some of these products were formed only

in very small quantities. Similar products were found as a result of the reaction of Aerozine-50 with hypochlorite. The reaction of iodine solution with hydrazine vapors has been used for the quantitative analysis of MMH and UDMH [299].

#### 1.4.10.12 Reactions of UDMH with Peroxydisulfate

The best method of UDMH removal is complete mineralization, leaving only innocuous  $\text{CO}_2$  and  $\text{H}_2\text{O}$  as end products. The oxidation of UDMH with peroxydisulfate in the presence of nano-iron as a catalyst was optimized for operational parameters such as iron dosage, pH, and an initial amount of peroxydisulfate [300]. The optimum conditions were pH 3.45, peroxydisulfate = 836 mg/L and nano-iron = 158 mg/L. A computer model predicted that 91% of the UDMH would be converted by mineralization at a reasonable cost compared to other treatment methods.

#### 1.4.10.13 Kinetics of Oxidation of UDMH in Solution

The use of dimethylnitrosamine (NDMA) in the manufacturing of UDMH is now largely avoided. However, there is continued concern that the oxidation of UDMH (which was made by other safer processes) released to the environment or during processes of decontamination might again form nitrosamines. The oxidation of UDMH by air, hypochlorite, bromate, iodine, or ozone has been extensively studied [284], however, the kinetics of each reaction are different and would require additional investigation. The kinetics of the oxidation of UDMH and the composition of the reaction products depend on the type of oxidant and the reaction conditions (mostly the pH). The oxidation of 1,1-dialkylhydrazines usually results in the formation of tetraalkyltetrazenes, which are intensely yellow-colored compounds

Of these, the tetramethyltetrazene has been most thoroughly investigated (see chapter “Alkylhydrazines” in *Encyclopedia of Liquid Fuels*). When measuring absorption spectra of tetramethyltetrazene as a function of pH and while looking for a method for the analysis of UDMH, it was discovered that tetramethyltetrazene dissociates to a diazene. In an acidic solution, this is stabilized as its protonated form, which is a dimethyl diazenium cation [171]:

Oxidation of UDMH in acidic solution with potassium bromate, neutralization, ether extraction, and purification by vacuum distillation produced tetramethyltetrazene in 60–90% yield [301]. Similar results were obtained with 1,1-diethylhydrazine or 1,1-di-*n*-propylhydrazine that were also converted to the corresponding tetraalkyltetrazenes. The reaction proceeds by way of  $(\text{CH}_3)_2\text{N}^+=\text{N}^-$ , which is a diazo-like compound that is

unstable and forms on decomposition of a freshly titrated UDMH-KIO<sub>3</sub> mixture, leading to additional KIO<sub>3</sub> consumption beyond the two-electron exchange stoichiometry. Spectrophotometric data support the tentative structure of R<sub>2</sub>N<sup>+</sup>=NH for the conjugate acid.

The oxidation of UDMH with iodine in neutral or weakly basic solutions, using Mg(OH)<sub>2</sub>, CaCO<sub>3</sub>, or piperidine to absorb the formed HI acid, leads to tetramethyltetrazene in at least 77% yield [171]. The decomposition of tetraalkyltetrazenes in acid solutions according to

leads to primary and secondary amines. When comparing the rates of reaction of a homologous series of tetraalkyltetrazenes, it was found that the rate of hydrolysis by acids is inversely proportional to the basicity constant [302]. The reaction proceeded as a first-order reaction until it reached at least 30% decomposition, as measured by UV absorption, nitrogen gas evolution, and NMR spectroscopy. In many cases, first-order kinetics held true up to 90% decomposition. The rate of hydrolysis remained constant at pH 1.0–5.0 but dropped sharply above pH 5.

Spectrophotometric data supported the tentative conclusion of R<sub>2</sub>N<sup>+</sup>=N<sup>−</sup> and suggested the formation of an ion pair in hydrochloric acid solution [303]. When a mixture of dimethyldiazonium chloride and diethyldiazonium chloride was neutralized, three different tetraalkyltetrazenes were obtained:

This experiment indicated that the ions are freely interchangeable entities in acidic solution, which dimerize when the pH is raised. The three tetraalkyltetrazenes were separated by GC.

Radical cations of UDMH or MMH were generated by reaction of UDMH or MMH with cerium(IV) in sulfuric acid solutions in a fast-flow mixing chamber. The electron spin resonance (ESR) spectra of these short-lived intermediates were recorded and experimental nitrogen and proton coupling constants were determined [304]. Under some conditions, oxidation of UDMH led to the radical cation of tetramethyl-2-tetrazene. Molecular orbital calculations for molecules were performed and implications for reaction mechanisms for the oxidation of the hydrazines were explained.

Oxidation of UDMH in aqueous solution at 273 K with copper(II)chloride forms the purple complex

This diamagnetic complex has been identified by elemental analysis, IR, and PMR spectroscopy [252, 305]. Hydrolysis of the 1,1-dimethyldiazene complex with ammonia or hydrochloric acid forms tetramethyl-2-tetrazene.

#### 1.4.10.14 Electro-Oxidation of UDMH

In addition to procedures using chemical oxidants, the oxidation of UDMH can also be achieved by electrochemical oxidation. This could serve the destruction of UDMH, act as an analytical tool, or go toward explaining the oxidation/reduction potentials of hydrazines. Controlled potential electrolysis of UDMH on smooth platinum electrodes in 1 M sulfuric acid yielded two electrons per UDMH molecule, according to the overall stoichiometry [306]:

However, the reaction proceeded after undergoing several intermediate steps. The rate-determining step was a single-electron adsorption-desorption stage, as indicated by a slope of the Tafel curve of 110 mV per current decade. The reaction orders for UDMH and  $\text{H}^+$  were 0.54 and  $-0.55$ , respectively. The diazonium salt was comparatively stable and could be identified in the solution following the test.

In a study of the anodic oxidation of UDMH on gold electrodes in 0.5–1.0 N sulfuric acid solutions, the experimental apparatus was the same as that previously used for a study on the oxidation of hydrazine [307]. Potential measurements in the range of  $-0.4$  to  $+1.0$  V (against  $\text{Hg}/\text{Hg}_2\text{SO}_4$  electrode) revealed three oxidation peaks [308]. The first peak was a well-defined irreversible oxidation threshold. A mechanism was proposed for this first step, which was most likely a two-electron transfer in acidic milieu:

This led to the diazenium cation that had already been observed in the chemical oxidation of UDMH. The remaining electrochemical oxidation steps were less well-defined than the first step. Earlier studies of the electro-oxidation of MMH had used a dropping mercury electrode in alkaline solution [309] and a gold electrode in acidic solution [310].

The electro-oxidation of UDMH on platinum has been studied in non-aqueous solvents such as dimethylsulfoxide [311] or acetonitrile [312, 313]. The latter report also included the oxidation of trimethylhydrazine. In alkaline solutions, hydrazine undergoes a quantitative four-electron oxidation process, while its methyl derivatives are oxidized quantitatively to the corresponding diimides in the same media. The anodic oxidation of MMH and UDMH on carbon fiber electrodes was studied in acetonitrile as a non-aqueous solvent [314].

Three different methods were used to study the anodic oxidation of UDMH: cyclic voltammetry, controlled potential electrolysis, and potentiostatic step measurements

[315]. The oxidation was achieved on smooth platinum electrodes in 1-*M* sulfuric acid or 2*M* perchloric acid.

#### 1.4.10.15 Reactions of UDMH with Organic Compounds

Many of the reactions, such as the reaction with acyl halides or carbonyl groups, are observed with alkylhydrazines (MMH, UDMH) and hydrazines alike. UDMH reactions and applications were summarized in a product brochure [93, 316].

Methyl groups increase the nucleophilic reactivity of the substituted position of hydrazines and reduce the nucleophilicity of the adjacent nitrogen center [317]. As a result, the tertiary nitrogen atom of 1,1-dimethylhydrazine is 3000 times more reactive than the NH<sub>2</sub> group, however, under thermodynamic control, substitution of an NH<sub>2</sub> proton can occur. The *N,N*-dimethylhydrazones of 37 carbonyl compounds were prepared and characterized by their boiling points, refractive indices, and IR spectra [318].

The reaction of aldehydes with excess UDMH can be used for the analysis of aldehydes by back titrating with HCl with thermometric endpoint indication [319]. Aldehydes have been used as reagents in the analysis of hydrazines but the inverse can also be the case when hydrazines are used in the analysis of aldehydes [320]. A common example is the analysis of sugars by derivatization with 2,4-dinitrohydrazine.

The melting points, decomposition temperatures, and ignition delays of 14 different solid hydrazones derived from UDMH were measured because these solid compounds were considered as fuels for hypergolic hybrid rockets [321]. Reaction of dimethylchloramine with UDMH leads to triazanum salts, which are unwanted by-products that limit the UDMH yield [49].

Amination of UDMH with NH<sub>2</sub>Cl or hydroxylamine-*O*-sulfonic acid yields 2,2-dimethyltriazanum (DMTZ) chloride and sulfate, respectively. The DMTZ cation was paired with the nitrogen-rich anions 5-aminotetrazolate, 5-nitrotetrazolate, 5,5'-azobistetrazolate, and azide, yielding a new family of energetic salts [322].

*N,N*-Dimethylhydrazones are useful intermediates in organic syntheses. Carbonyl group is often protected from unwanted side reactions by temporarily forming the dimethylhydrazone, such as during  $\alpha$ -alkylation, followed by hydrolysis of the hydrazone on silica gel [323].

Reactions of surplus UDMH with epoxides could lead to aminimines and aminimides. These can be used as intermediates for the synthesis of a number of other organic compounds

Eight saturated aliphatic aminimides with low melting points were synthesized after UDMH was alkylated, acidylated, and dehydrogenated [324]. The preparation and applications of aminimides are an effective approach to making good use of surplus UDMH [325]. In search for useful applications for surplus UDMH as part

of a demilitarization effort, it has been proposed to use UDMH for the synthesis of polyurethanes [326, 327].

#### 1.4.10.16 Alternative Uses for Surplus UDMH

Burning or spending money on aggressive chemicals capable of destroying UDMH has had mixed results and has produced a generation of unwanted and even more toxic by-products. As such, there have been numerous efforts to find alternative uses for UDMH (and  $N_2O_4$ ), with entire conferences being devoted to this topic [328]. 1,1-dimethylcarboxylic acids convert to dihydrazides. Glycidyl esters of carboxylic acids form *N*-acyl-*N'*,*N'*-dimethyl-*N'*-(2,3-dihydroxypropyl) zwitterions that rearrange to form 2,3-dihydroxypropyldimethyl amine [329]. One most unusual proposal was to react  $N_2O_4$  with agricultural waste and then react that mess with UDMH, which would result in a storable solid [330].

One of the potential uses of surplus UDMH is the synthesis of surfactants [331]. Long-chain ammonium imides derived from UDMH have surfactant and emulsifier qualities. Starting with surplus UDMH, many commercial products were synthesized successfully, including daminozide, 1,3,5-triamino-2,4,6- trinitrobenzene (TATB), heterocyclic compounds, organosilicon derivatives, and trifluoromethanesulfonic hydrazide [332].

Catalytic reduction of surplus UDMH diluted with an inert solvent (e.g., methanol) with hydrogen over Group VIII transition metal catalysts can lead to DMA and ammonia. Both of these are marketable and useful chemical raw materials that can act as reaction products [333–336].

UDMH and other energetic materials can be converted to chemicals that are useful in other synthesis reactions [337–339]. 1,1,1-Trimethylhydrazinium iodide made from UDMH is the most efficient nucleophilic aminating reagent available for the synthesis of TATB by vicarious nucleophilic substitution reactions starting with picramide. The reaction of UDMH and alkyl chlorides forms 1,1-dimethyl-1-alkylhydrazinium chlorides which are useful intermediates for the synthesis of other compounds [340] (see also [341, 342]).

#### 1.4.11 Analysis of Unsymmetrical Dimethylhydrazine

Very sensitive analytical methods for the detection and quantification of traces of UDMH in environmental samples include GC, HPLC, and ion chromatography (IC) [343].

##### 1.4.11.1 Specifications for UDMH

Procurement of UDMH was covered by MIL SPEC specification MIL-PRF-25604E [344]. MIL SPEC specification requirements for UDMH are listed in Table 14. Foreign countries have developed their own specifications for UDMH [345, 346] (see also [347]).

**Table 14:** MIL SPEC specification requirements for UDMH.

| Property                                      | Requirement    |
|-----------------------------------------------|----------------|
| UDMH assay, mass-%                            | 98.0 minimum   |
| Water, mass-%                                 | 2.0 maximum    |
| Amines, mass-%                                | 1.5 maximum    |
| NDMA, mass-%                                  | 0.01 maximum   |
| Chloride, mass-%                              | 0.003 maximum  |
| Density at 288.7 K (60 °F), g/cm <sup>3</sup> | 0.795 to 0.797 |
| Particulate, mg/L                             | 10 maximum     |

#### 1.4.11.2 Chromatographic Analysis Methods for UDMH

##### Gas Chromatographic Analysis Methods for UDMH Without Prior Derivatization

UDMH assay per MIL SPEC can be determined by GC on a 1/8 in. outer diameter (O.D.) × 6-ft packed column filled with 10% PEG400 on Fluoropack 80. NDMA content per MIL SPEC can be determined by GC in a 1/8 in. O.D. × 6-ft packed column filled with 33% Alltech AT-220 (formerly Amine 220) on 70/80 mesh silanized white diatomaceous earth.

The stability of UDMH is greatly affected by the presence of impurities. Most organic impurities are present in the propellant from when it is manufactured. To assess the likely range of impurities, a review of manufacturing methods for propellant hydrazines was undertaken. This was followed by a stability assessment and impurity survey (using GC-MS) on samples of MMH and UDMH from four different sources [266]. It was concluded that impurity profiles and stability are greatly affected by the manufacturing method.

Apparently some third world countries, in their quest for more UDMH, resorted to the direct methylation of hydrazine with dimethyl sulfate. As a result, they obtained mixtures containing four methylated derivatives of hydrazine, MMH, UDMH, SDMH, and trimethylhydrazine, with some unreacted hydrazine and water that needed to be analyzed by GC [348]. Several columns with different stationary phases under different experimental conditions (temperature ramping, carrier gas flow, split/splitless injection) were used. However, clearly resolved peaks of proper peak shape and integration could not be obtained.

A review of the existing methods for determining hydrazine and its short-alkyl and acyl derivatives with the use of different types of chromatography devoted special attention to the selectivity and sensitivity of the suggested approaches [349, 350]. Possible ways to increase the sensitivity of hydrazine determination were suggested and evaluated against real samples that were previously analyzed.

There are many types of highly sensitive chromatographic methods that can be applied to the detection of UDMH contamination in water and soil [351]. The peaks eluting from the GC were identified by mass spectrometry. Contaminants identified in UDMH included dimethylamine, FDMH, and nitrosodimethylamine. Samples containing mixtures of hydrazine, MMH, and UDMH can be separated after derivatiz-

ing the sample with acetone. Rinse waters from a test facility stored in catch tanks and not inerted with nitrogen padding (that is they were exposed to air before samples were taken) were analyzed by GC/MS. The waste products identified included acetaldehyde dimethylhydrazone, acetone dimethylhydrazone, nitrosodimethylamine, dimethylaminoacetonitrile, acetone methylhydrazone, *N,N*-dimethylformamide, acetone azine, 1-methyl-1*H*-1,2,4-triazole (MTA), guanidine, dimethyltriazole, tetramethylurea, and glyoxal bis(dimethylhydrazone).

A method for the analytical extraction of mobile species of eight main transformation products of UDMH (FDMH, acetaldehyde dimethylhydrazone, 2-furaldehyde dimethylhydrazone, 1,1,4,4-tetramethyl-2-tetrazene, *N,N*-dimethylformamide, NDMA, MTA, and 1-formyl-2,2-dimethylhydrazine) from soils using sub-critical acetonitrile at a pressure of 100 bar had recoveries of analytes that were better than 70% at an extraction time of no more than 30 minutes [352]. The effects of temperature, number of extraction cycles, and the moisture content of soil samples on the recovery of analytes were studied. It was found that, for soils with high concentrations of lignin humic substances, efficient extraction can be attained with an addition of significant amounts of alkali to the soil (2.5 g/g). A combination of the proposed sample preparation/extraction approach with analysis by GC-MS/MS ensured the accurate determination of the products of UDMH transformation in complex matrixes, such as soils with high contents of organic substances, with detection limits from 1.8 to 15 µg/kg using the direct injection of the extract into the GC system.

GC/MS analysis of UDMH and initial autoxidation products discovered that the oxidation sample contained dimethylamine, UDMH, FDMH, NDMA, acetaldehyde dimethylhydrazone, 1,1,4,4-tetramethyl-1,2-tetrazene, and dimethyldiazene with oxidation times of <100 h in air. The content of dimethylamine, FDMH, and NDMA increased in this stage but the content of DMA eventually decreased [353]. Solid-phase micro-extraction (SPME) combined with GC/MS was applied to the analysis of degradation products in water that was contaminated by UDMH [354]. The accuracy of gas chromatographic determination of UDMH can be improved by mixing UDMH with an internal standard solution [355].

### Gas Chromatographic Analysis Methods for UDMH with Prior Derivatization

Gas chromatographic analysis methods for UDMH with prior derivatization are summarized in [356]. Derivatizing reagents include 2-furaldehyde [357–359], pentanedione [360], acetone [361], 2-nitrobenzaldehyde, 4-nitrobenzaldehyde, 4-chlorobenzaldehyde, 4-cyanobenzaldehyde 4-dimethylaminobenzaldehyde, benzaldehyde, furfuraldehyde [362], salicylaldehyde [363], or alkyl isothiocyanates [351].

Analysis of a UDMH sample using GC/MS and GC/FTIR spectroscopy yielded a total-ion chromatogram with two major, three smaller, and six much smaller peaks, in addition to those due to the solvent and the UDMH itself [298]. The two major impurities were unambiguously identified as DMA from its published mass spectrum, and formaldehyde *N,N*-dimethyl hydrazone from its published IR spectrum. One of

the intermediate peaks was also unambiguously found to be chloromethane. The remaining intermediate peaks were postulated to be formaldehyde *N*-methylhydrazone and formaldehyde *N,N*-methylethylhydrazone based on their mass spectra. The remaining minor impurities could not be identified. The origin of the chloromethane is unclear. Because it was found in all the methylated fuel samples, it was presumably a residual from some common step in the manufacturing process for MMH and UDMH using the Raschig process.

The GC separation of the two isomeric dimethylhydrazines and the separation of UDMH from its oxidation products, i.e., tetramethyltetrazene and nitrosodimethylamine, can be improved by pre-treating the stationary phase with strong alkali [364].

The components of UDMH in liquid propellants were analyzed by GC/MS [365]. The retention ratios of the fractograms and the fragmentation mechanism of the mass spectra of components were studied for each component. The result showed that the UDMH in liquid propellant contains impurities of water, unsymmetrical dimethylhydrazone, dimethylamine, and acetaldehyde dimethylhydrazone. Except for dimethylamine, other impurities will reduce the specific impulse of the propellant.

Carbon dioxide in UDMH or MMH can be determined by adding a solution of barium chloride. The mass ratio of sample to be analyzed and barium chloride added should be  $1:5 \times 10^{-3}$  to  $1:1.7 \times 10^{-3}$ . The mixture should be placed into a rotavapor for vacuum distillation from a water bath at 313–318 K (40–45 °C) and heated to dryness. Distilled water should then be added to the dry residue, which leads to a mixed solution. The optical density of the said solution is determined with the help of photocolourimetry procedure at  $\lambda = 400$  nm [366]. Chloride in UDMH can be analyzed by the method described in MIL-PRF-25604E by reacting the sample with mercury(II) thiocyanate and analyzing the excess thiocyanate with iron(III) ammonium sulfate spectrophotometrically [344].

#### HPLC of UDMH Without Prior Derivatization

Hydrazine, MMH, UDMH, and SDMH can be separated and determined by ion-exchange HPLC using an electrochemical detector with a glassy carbon working and auxiliary electrodes [367]. The hydrazines do not require derivatization. Urine or blood plasma samples suspected of containing these compounds may be analyzed directly without previous work-up.

Solid-phase extraction (SPE) has been used for sample pre-treatment followed by HPLC analysis of the metabolites of UDMH in the blood of Wistar rats [368]. The blood before UDMH intoxication was collected as control and treated.

A liquid chromatography/MS method was developed for determining the transformation products of UDMH in soils, including formic acid dimethylhydrazide (= 1-formyl-2,2-dimethylhydrazine, analytical range 0.01–20 mg/kg), 1-methyl-1,2,4-triazole (analytical range 0.05–100 mg/kg), 1,1-dimethylguanidine (analytical range 0.05–100 mg/kg), and DMA (analytical range 0.25–250 mg/kg) [369]. The measurements were performed in the mode of chemical ionization under atmo-

spheric pressure, followed by the registration of positive ions corresponding to the protonated forms of the components to be determined. For sample pre-treatment, the use of extraction with methanol (for 1-formyl-2,2-dimethylhydrazine) and ultrasonic extraction with a weakly alkaline buffer solution (for other substances) was proposed.

A liquid chromatography-tandem MS method for the simultaneous determination of MMH, UDMH, *N,N*-dimethylformamide, MTA, dimethylguanidine, NDMA, and 1,1,4,4-tetramethyltetrazene (all important rocket fuel pollutants of soils near rocket launch sites) used an isocratic mode on an analytical column with a Nucleosil-100-5SA sulfo cation-exchanger [370]. The mobile-phase composition was optimized to achieve effective separation of all analytes and to provide a high sensitivity of mass spectrometric detection. An ammonium acetate buffer solution (50 mM, pH 5.4) containing 25% methanol was used. Detection was performed in the positive electrospray ionization mode with multiple reaction monitoring (MRM). The parameters of an ion source, ion optics, the inlet potentials of the quadrupoles, and the collision energy for the detection of the detected product ions were optimized. Calibration curves for all compounds were linear in wide concentration ranges, covering three to four orders of magnitude. The detection limits varied from 40 pg/mL for dimethylguanidine to 18 ng/mL for MMH. No significant matrix effects were observed in the analysis of acid peaty soil extracts. The method was validated and successfully used to analyze real soil samples collected at the location of impact of the first stage of a space launch vehicle rocket.

A hydrophilic interaction liquid chromatography (HILIC) method for the simultaneous determination of hydrazine, MMH, and UDMH in natural waters and soils, based on a combination of HPLC chromatographic separation on a zwitterionic sulfobetaine stationary phase with amperometric detection, used a mixture of 78 vol. parts of acetonitrile with 22 parts of an aqueous phosphate buffer solution of pH 2.5 with an ionic strength of 20 mM as the mobile phase [371, 372]. This method allows simultaneous and rapid determination of UDMH and six major products of its transformation (methylhydrazine, NDMA, *N,N*-dimethylformamide, 1-methyl-1,2,4-1*H*-triazole, 1,1,4,4-tetramethyl-2-tetrazene, and 1,1-dimethylguanidine). Detection in the direct current mode was performed at a working electrode potential of 1.1 V. The advantages of the method are the high efficiency of separation, speed, high sensitivity, and a wide dynamic range of analyte concentrations, covering four orders of magnitude. The limits of detection were in the range of 0.07–0.13 µg/L. This was two orders of magnitude lower than those achievable in previously used methods of IC with electrochemical or mass spectrometric detection. The method was validated on samples of natural waters of different origins with added internal standards. The error of analysis did not exceed 10% for river and ground waters but increased to 20–30% for peat bog swamp waters. The utility of the method was demonstrated with samples of peat bog soils collected from places polluted by UDMH from the impact of the first stages of space launch rockets.

### IC Methods for the Analysis of Alkylhydrazines

An earlier example of separation of the three hydrazines by IC was already detailed in the chapter “Hydrazine” in *Encyclopedia of Liquid Fuels*. Analysis by IC uses equipment that is similar to HPLC. IC with amperometric detection was applied for the direct determination of UDMH, hydrazine, MMH, and SDMH in water [373]. Selectivity of two column materials, **(1)** a reversed-phase silica modified by dodecylbenzenesulfonic acid and **(2)** silica with chemically-bonded sulfonic acid, groups were investigated with conductivity detection. An example of the separation of the four hydrazines is shown in Figure 16. A detection limit with a 0.5 mL sample injection for UDMH was 2.0 ppb. The method was used for the analysis of soils contaminated by spilled UDMH from crashed Proton launch vehicles. Hydrazine and MMH were detected as decomposition products of UDMH in the soil.

**Figure 16:** Ion chromatogram of hydrazine, MMH, UDMH, and SDMH separation in water. (Reprinted and adapted from [373], with permission from ©2002 Japan Society for Analytical Chemistry)

One method for the determination of UDMH in soil samples involved the distillation of UDMH from an alkaline suspension of soil and ion chromatographic analysis of the distillate [374]. The separation was performed on a silica cation-exchanger column with an ammonium acetate buffer solution as part of the mobile phase and with amperometric detection at +1.2V. Hydrazine and MMH, which are decomposition products of UDMH, can be determined simultaneously. The limits of detection in aqueous solutions were 0.2, 0.5, and 1 µg/L for  $N_2H_4$ , MMH, and UDMH, respectively. The method was used for investigating the behavior of UDMH in spills of rocket fuels on soils. It was found that the addition of 4 kg/m<sup>2</sup> UDMH resulted in a 0.02% residue, which survived one year after the soil inoculation. The vertical migration of UDMH in soil was less than 50 cm. The ion-exchange constants for ion-chromatographic retention of 16 aliphatic amines and hydrazines on Diasorb-130-Sulfo and Nucleosil 5 SA were calculated. The selectivity of the retention of these compounds was compared

and optimum conditions of detection were determined [375]. Mass-spectrometry detection was used for compound identification after the chromatography separation and the characteristics of the mass spectra of the aliphatic amines and hydrazines were presented.

A study of the influence of eluent composition (the nature and concentration of the ion-pair reagent, medium pH, the concentration of the buffer solution, and the content of acetonitrile) on the retention of UDMH and its decomposition products on hydrophobized silica gels under the ion pair chromatography conditions was studied. This revealed that, for these sorbates, the influence of ion-pair reagents can be described correctly in terms of stoichiometric models [376].

The simultaneous determination of UDMH and its decomposition products hydrazine, methylhydrazine, NDMA, and tetramethyl-2-tetrazene with detection limits in water matrices at concentrations of 0.3, 0.7, 0.8, 7, and 1.2 µg/L, respectively (sample volume of 100 µL), is possible using ion-pair chromatography by means of sodium octylsulfate, octylsulfonate, or dodecylsulfate as an ion carrier [377]. Sodium octylsulfate was preferable as an ion-pair reagent.

There are several methods for the direct determination of hydrazines in water, including ion, ion-pair, ion-exclusion, and hydrophilic interaction chromatography [378]. The separation selectivity and sensitivity of detection for each method depend on the type of samples. Direct methods are simpler than those requiring prior derivatization of the samples, as was demonstrated with examples of hydrazine(s) determinations in real samples.

UDMH and products of its transformation in aqueous solutions can be analyzed with ion and ion-pair chromatography and mass-spectrometric detection in the electrospray ionization mode [379]. It has been shown that up to seven components may be determined within the limits of detection at the µg/L level. These methods were applied to the analysis of solutions with an initial UDMH concentration of 500 mg/L that had undergone autoxidation by atmospheric oxygen. Formic acid dimethylhydrazide, 1-methyl-1,2,4-triazole, and DMA were found among the autoxidation products [380].

Supercritical fluid extraction of UDMH from peaty soils with carbon dioxide is a rapid method of sample preparation for ion-chromatographic analysis [381].

IC with conductivity detection was used to directly analyze UDMH in wastewater, without any derivatization pre-treatment [382]. Column temperature, sample pH, different combinations of nitric acid, 2,6-pyridinedicarboxylic acid, and methanesulfonic acid on the analysis of mixed samples of UDMH and alkali metal ions were optimized. The linearity of the detected peak height (H) and peak area (A) versus UDMH concentration was studied at low, medium, and high concentrations. A good linear relationship was observed in the range of 0.5 – 1000 µg/mL. The limit of detection was 0.05 µg/mL. Actual UDMH in water samples from a rocket test site were analyzed, verifying the applicability of the method for analyzing UDMH in wastewater during the degradation process.

### HPLC of UDMH with Prior Derivatization

HPLC methods for the analysis of UDMH with prior derivatization have already been summarized in [383]. Most of the derivatizing agents described for hydrazine in this volume within the chapter “Hydrazine,” have also been examined for the presence of UDMH or MMH. Reagents used for the derivatization of UDMH included salicylaldehyde [384–386], benzaldehyde [387, 388], 2-nitrobenzaldehyde [389], 4-nitrobenzaldehyde [390], glyoxal or phenylglyoxal [391, 392], naphthalene-2,3-dialdehyde [393], and formaldehyde [394].

#### 1.4.11.3 Volumetric Methods for the Analysis of UDMH

UDMH is a weak base with a  $pK_a$  of  $8.19 \pm 0.18$ . Other sources reported it as 7.13 [249]. One will have to select the correct indicator if titrating UDMH acidimetrically.

#### Acidimetric Titration Following Reaction with Carbonyl Compounds

The  $pK$ 's of hydrazine and UDMH or MMH are too close to each other to allow simultaneous titration of mixtures of two or three bases in an aqueous solution. Following derivatization of hydrazine and UDMH, however, the acidity of the resulting azines (when titrated in non-aqueous media such as acetic acid) with perchloric acid in dioxane is distinctly different as it forms separate end points. Derivatization allows separate titration of different hydrazines and may also help in achieving sharper end points. Carbonyl compounds used to derivatize hydrazines in this application include salicylaldehyde [395–400] and acetone.

Instead of forming derivatives with salicylaldehyde, the different rate of acetylation of hydrazine and UDMH or hydrazine and MMH with acetic anhydride provides for a method to analyze binary hydrazine mixtures [401, 402]. In acetonitrile (as the solvent), both hydrazine and MMH react almost immediately, whereas the acetylation of UDMH proceeds very slowly. The total basicity of an unacetylated sample is determined by titration with standardized perchloric acid in acetic acid with quinaldine red indicator.

Hydrazine and its methylated derivatives can be differentiated, not only by reaction with acetylating agents or azine-forming reagents, but also by acidimetric titration before and after reaction of the sample with isocyanates [403, 404]. The reaction of hydrazines with alkyl or aryl isocyanates leads to semicarbazides, which are weaker bases than the parent hydrazines. In an alcoholic solution, hydrazine, MMH, and UDMH react with isocyanates at approximately the same rate to form semicarbazides. In contrast, in anhydrous acetic acid, hydrazine and MMH react rapidly but UDMH hardly reacts at all. Suitable isocyanates for masking hydrazine or MMH are phenyl isocyanate or naphthyl isocyanate.  $N_2H_4$ -UDMH and  $N_2H_4$ -MMH mixtures were titrated by this method and the error very rarely exceeded 0.5% absolute.

Formaldehyde dimethylhydrazone,  $H_2C=NN(CH_3)_2$ , FDMH, is a degradation product and contaminant of UDMH. Both UDMH and FDMH are colorless. When titrated with perchloric acid in acetic acid, both UDMH and FDMH have the same basicity.

When titrated with methanolic HCl in methanol, only UDMH acts as a base. The difference can be used for the determination of FDMH contamination in UDMH [405].

Attempts to determine total water content in UDMH by a gasometric method by reaction with calcium hydride failed because calcium hydride reacted not only with the water, but also (very slowly) with UDMH [406–408]. Gas evolution with calcium carbide has been measured as an alternate.

#### 1.4.11.4 Redox Titration Methods for UDMH

Most of the analysis methods described in older documents are now obsolete and have been replaced by more accurate instrumental methods. Attempts to apply iodine or iodate titration methods (which worked satisfactorily with hydrazine  $\text{N}_2\text{H}_4$ ) to the analysis of MMH or UDMH have not always been successful at the first attempt. Lower temperature and/or the addition of catalysts may be required to achieve sharp endpoints. Direct titration of UDMH with  $\text{KIO}_3$  is possible if one operates in concentrated HCl and a saturated solution of mercury(II) chloride is added as a catalyst [409].

Titration of hydrazines with  $\text{KIO}_3$  can lead to end points of iodine(+1) in  $\text{ICl}$  or iodine(–1) in  $\text{KI}$ , depending on the pH conditions. It is very difficult to achieve a sharp end point in these titrations [410, 411]. Acidity, sample size, temperature, amount of mercury catalyst, and time spent to reach the endpoint must be carefully controlled, with acidity maintained at above 2N HCl. The endpoint can be detected by the blue color formed by starch with the first free iodine formed from excess iodate and iodide. Potentiometric endpoint indication is also possible. The potential jump at the equivalence point is from 0.6 to 0.8 V. A dimethyldiazonium compound present in the solution at the endpoint will continue to consume iodate at a slow rate.

The potentiometric titration of hydrazine  $\text{N}_2\text{H}_4$  with iodate had previously been used only for uniform hydrazines. Also, attempts to use iodate titration for the analysis of UDMH alone has not always been successful. However, it was shown that by maintaining a high acid concentration and using potentiometric endpoint indication, it was possible not only to titrate UDMH by itself but also to determine the total number of redox equivalents (R) in  $\text{N}_2\text{H}_4/\text{H}_2\text{NN}(\text{CH}_3)_2/\text{H}_2\text{O}$  mixtures [412]. A parallel acidimetric titration gave the number of acid-base equivalents (A) in the sample. Repetitive titrations demonstrated that this method can be applied to the analysis of hydrazine-UDMH mixtures of 3% relative or better.

A Metrohm 809 automatic potentiometric titrator with potentiometric end-point indication was used to analyze UDMH [413]. The experimental results demonstrated excellent precision and accuracy and indicated that the proposed method is quite suitable for UDMH analysis. The results also were in good agreement with those using other standard methods.

#### 1.4.11.5 Electrochemical Methods for the Analysis of UDMH

Electrochemical analysis methods are becoming increasingly popular because they can be automated and will eventually interface with digital data acquisition and data reduction.

##### Coulometric Analysis Methods for UDMH

A rapid and automatic coulometric titration procedure for the determination of hydrazine and mono-substituted hydrazines with electrolytically generated bromine had a standard deviation of approximately  $\pm 1\%$  and was based on the use of the Faraday constant as a standard [414]. Samples in the 3–5-mg range could be analyzed. The use of anodically generated chlorine in place of bromine did not result in any improvements. An acetic acid/water/methanol/mercury(II)acetate/potassium bromide solvent was used for most of the compounds titrated. Other solvents tested were aqueous 0.3M hydrochloric acid with 0.1M potassium bromide and 80% acetic acid/20% water 1.0M in hydrochloric acid with potassium bromide. The choice of solvents depends on the type of hydrazine to be titrated. Unsymmetrical dimethylhydrazine consumed close to six (5.88) equivalents. The results were reproducible; SDMH, however, produced erratic results and could not be analyzed using this procedure.

A similar method in a microcell holding a small 0.5 mL sample volume has extended the range to micromol quantities of hydrazine(s) [415]. All three propellant hydrazines (hydrazine, MMH, and UDMH) from sulfuric acid-impregnated air sampling tubes or wastewater samples could be analyzed and titrated coulometrically with electrically generated chlorine or bromine, but the method did not differentiate between the three hydrazines [416]. This method is faster than many competing methods since it does not require derivatization and has no internal standards for calibration. At the lower limit of sensitivity, nanomols of hydrazines can be detected, which translates to ppb concentrations in air samples. The coulometric titration does not differentiate between hydrazines and hydrazones, which are contaminants in the sample. In samples that contain MMH and UDMH autoxidation and partial oxidation products, various amounts of formaldehyde hydrazones will be found that may also consume oxidant. Formaldehyde and its hydrazones are also oxidized by either free chlorine or bromine but the stoichiometry is different from that with pure hydrazines. In samples with large amounts of methylhydrazines and their autoxidation products, the coulometric titration results can be corrected by separately determining formaldehyde (from the hydrolysis of the methylhydrazones) colorimetrically with chromotropic acid in concentrated sulfuric acid [416].

##### Polarographic Analysis Methods for UDMH

A measurement of the half-wave potentials of hydrazine, two hydrazides, six alkylhydrazines, and phenylhydrazine in 0.1M NaOH showed that the potentials for UDMH and SDMH were essentially identical and more negative than expected for ethylhy-

drazine [417]. The currents for these two dimethylhydrazines indicated a two-electron rather than a four-electron mechanism.

In an investigation on the polarographic determination of hydrazine derivatives with a dropping mercury electrode, anodic waves were obtained for most monoalkyl-, acyl-, dialkyl-, and acylalkyl-hydrazines in alkaline medium [418]. However, the quality and analytical usefulness of these waves varied widely. Only the unsymmetrically dialkyl-substituted hydrazines produced waves that were suitable for analytical purposes in the presence of sulfite ions. Hydrazine  $\text{N}_2\text{H}_4$  itself and MMH formed only distorted waves.

Methylamine, UDMH, and dimethylamine, which may be found in the effluent water of a UDMH production facility, can be determined simultaneously by polarography on a dropping mercury electrode in a lithium perchlorate solution/borate buffer electrolyte [419]. Oxidation of these compounds involved two electrons in all cases. The effluents may also contain formaldehyde, which is frequently an autoxidation or hydrolysis product of UDMH or tetramethyltetrazene. Formaldehyde (up to a tenfold excess) did not interfere with the analysis.

### Electro-Oxidation of UDMH in Solution

UDMH, as well as hydrazine, both show a large overpotential associated with electro-oxidation at conventional electrodes. Electrochemical analysis of hydrazines is a major challenge that calls for the development of high-performance catalysts to facilitate the oxidation process. In analogy to the studies on hydrazine, the electro-oxidation of UDMH and SDMH at a platinum electrode has been investigated using chronopotentiometry, coulometry, and product analysis [420]. The results of this study bear certain significance for the attempted polarographic analysis of these compounds. The results showed that oxidation of SDMH proceeds through an initial two-electron oxidation, followed by hydrolysis to formaldehyde and methylhydrazine. Unsymmetrical dimethylhydrazine becomes oxidized through a two-electron process to 1,1-dimethyldiazene, which undergoes a relatively slow chemical decomposition, possibly through rearrangement

forming a hydrazone. A third possible reaction involves coupling to the tetrazene:

The measurements were done with an experimental set-up that can collect, measure, and analyze gaseous electrolysis products of alkylhydrazines [421].

Three different methods were used to study the anodic oxidation of UDMH: cyclic voltammetry, controlled potential electrolysis, and potentiostatic step measurements [422]. The oxidation was achieved on smooth platinum electrodes in 1M sulfuric acid or 2M perchloric acid.

The electrocatalytic oxidation of UDMH on a prussian blue modified carbon paste electrode was studied using a cyclic voltammetry technique [423]. The results showed that prussian blue acts as a suitable modifier for electron transfer in the oxidation of UDMH. A linear range of  $3 \times 10^{-5}$  to  $1 \times 10^{-3}$  mol/L, with a limit of detection ( $3\sigma$ ) of  $1.6 \times 10^{-5}$  mol/L, was obtained using the amperometric method. The proposed sensor did not suffer from interference from hydrazine, was easy to prepare, and had good stability and repeatability. This electrode was successfully applied to the determination of UDMH in wastewater samples.

A Prussian blue/titanium dioxide nanotube composite modified carbon paste electrode for the detection of UDMH in water, based on prussian blue as the catalyst to promote oxidation of UDMH, had a linear range of 0.3–100 mg/L and a limit of detection of  $2.6 \times 10^{-5}$  g/L [424].

### Dielectric Constant Analytical Methods

If the dielectric constants of two components in binary mixtures are sufficiently disparate, and if the interference by third parties can be eliminated, measurement of the dielectric constant of liquids offers a convenient and rapid analysis method of binary mixtures. Water content in UDMH can be determined with  $\pm 0.02\%$  absolute accuracy in the 0–2%  $\text{H}_2\text{O}$  range by measuring the capacitance of a liquid-filled cell [425, 426]. Similar measurements achieved an accuracy of 0.02% for 0–5%  $\text{H}_2\text{O}$  in UDMH [265]. The interference of DMA contamination in UDMH was identified as a minor effect. Unfortunately, the dielectric constants of mixtures in the 0–100% range for both  $\text{H}_2\text{O}$ -UDMH and  $\text{H}_2\text{O}$ - $\text{N}_2\text{H}_4$  mixtures were provided only in scale units of a particular model oscillometer that the investigators happened to use. The data were not presented in terms of the more commonly used Debye units for dielectric constants.

#### 1.4.11.6 Spectrophotometric Methods for the Analysis of UDMH

##### UV-Visible Spectrophotometric Methods for the Analysis of UDMH

Many of the spectrophotometric methods operating in the visible range have the advantage that they are easy to perform, are specific for hydrazines, and do not require very costly equipment. Therefore, for the analysis of trace quantities of UDMH in air or water, spectrophotometric methods are frequently used either for routine analysis or to calibrate electronic direct-reading instruments that are based on non-spectroscopic principles. They typically involve the reaction of a sample in water or dilute acid with a color-forming reagent that is more or less specific for UDMH.

Reagents for the spectrophotometric analysis of UDMH include formaldehyde [16, 405, 409, 427, 428], salicylaldehyde [429], chromotropic acid [416, 430, 431], trisodium pentacyano ammino ferrate(II) [432–439], 5-nitro-2-furaldehyde [440], and gold nanoparticles [441].

Hydrocarbon/UDMH mixtures can be analyzed after the sample is treated with an acetic acid aqueous solution at a mass ratio of water, sample, and acetic acid =

1:(0.33–0.89):(0.10–0.33), respectively. The hydrocarbon content is determined by photometry at wavelength  $\lambda = 400$  nm [442].

A solution of 0.1% hydrochloric acid was used as the absorbent in hollow fiber (HF) membranes for the sampling of UDMH from an atmospheric standard chamber, followed by spectrophotometric detection [443]. Response surface methodology with central composite design experiment design was used to optimize the sampling parameters such as flow rate and sampling time. Several analytical parameters, including breakthrough volume, storage time, and carryover effect of the HF membrane were investigated. The optimal sampling rate was 9.90 mL/min. To validate the proposed method, it was compared with the NIOSH 3515 method [444]. Good agreement between the two methods was found. The one-step HF membrane offered a high sensitivity for the sampling of UDMH in air.

### IR and Raman Spectrophotometric Methods for the Analysis in UDMH

Water obeys Beer's law in hydrazine hydrate, MMH, or UDMH. Using the 1.9- $\mu$ m absorption band of water, an IR-spectrophotometric analysis method has been developed that is applicable to mixtures containing 0.1–15% water [445]. DMA or nitrosodimethylamine do not interfere, however, methanol or ethanol would interfere if they were present in concentrations greater than 1%. One-centimeter quartz cells were used for these tests. The results can be expressed by

$$P = a + bA,$$

where  $P$  represents weight percent of water in the mixture,  $A$  is 100 times the absorbance, and  $a$  and  $b$  are constants as follows (all data for 1-cm path length):

$$\text{MMH} \quad a = -0.0062 \quad b = 0.01958$$

$$\text{UDMH} \quad a = 0.019 \quad b = 0.01994$$

If the sample temperature differed by less than 2K from that used during calibration, only minor deviations (<1%) were encountered. Oxygen must be excluded from the solutions to prevent autoxidation and the formation of additional water.

Water in UDMH or mixtures of UDMH and DETA can be determined by a differential IR spectrophotometric method where part of the sample is first carefully dried with molecular sieves and then placed in the reference beam [408]. The absorbance of the as-received sample at 1.93  $\mu$ m is measured in silica cells (path length of only 1 cm) and calibrated through samples with known water content. The standard deviation for water content between 0.1 and 1.2% was  $\pm 0.004\%$  absolute. Similar methods were sought for determining the water content of Titan-II propellants [446].

As far as the analysis of trace UDMH and other hydrazine vapors in the air by remote sensing IR methods is concerned, some of these methods are based on a tunable

laser as the source of the IR radiation. The  $^{12}\text{C}^{16}\text{O}_2$  laser can produce over 100 different discrete wavelengths between 9.1 and 11  $\mu\text{m}$  where there is very little interference from atmospheric water or carbon dioxide. UDMH has characteristic absorption bands in this regime [447]. The absorption spectra of three hydrazines and four of their air-oxidation products were measured in the 9–12  $\mu\text{m}$  spectral region with an FTIR spectrometer with a  $0.05\text{-cm}^{-1}$  resolution to determine absorption coefficients at  $\text{CO}_2$  and tunable diode laser wavelengths. The coefficients were then used to estimate the sensitivity for remote detection of UDMH vapors using  $\text{CO}_2$  and tunable diode lasers in long-path differential absorption measurements. Far-infrared group frequencies of unsymmetrical hydrazines were measured in the range of 450 to  $75\text{ cm}^{-1}$  [448].

### Fluorescence Methods for the Analysis of UDMH

The post-chemiluminescence reaction of UDMH in potassium bromate-luminol water solution and the reaction conditions, including the concentration of potassium bromate and luminol, the length of the tube, the velocity of the solution flow, the acidity ( $\text{H}_2\text{SO}_4$ ) of the potassium bromate solution, and the alkalinity ( $\text{NaOH}$ ) of the luminol solution were investigated to develop a new method for the determination of trace UDMH in water [449]. The linear response range of this method was from  $1 \times 10^{-7}$  to  $1 \times 10^{-5}$  g/L with a detection limit of  $4 \times 10^{-8}$  g/L. The relative standard deviation for a  $5 \times 10^{-7}$  g/L UDMH solution was 2.3%.

#### 1.4.11.7 Mass Spectrometric Analysis of UDMH

Ionization potentials of UDMH fragments in a mass spectrometer have already been detailed in the chapter “Methylhydrazine” of *Encyclopedia of Liquid Fuels*. UDMH, MMH, and hydrazine in the air can be detected and identified by ion mobility spectrometry (IMS) at low concentrations, however, there can be interference from ammonia [450]. The optimum spectrometer operating conditions for the detection of hydrazine, MMH, and UDMH in the presence of ammonia were incorporated into a handheld portable instrument capable of near real-time detection. The use of ketones as dopant chemicals has been shown to be effective in the ion mobility spectrometric determination of the hydrazines.

#### 1.4.11.8 Analysis of UDMH Contamination in Water and Soil

In most cases where UDMH contamination is analyzed in water or soils, one will want to know the concentration of undecomposed UDMH and the type and amount of UDMH degradation and autoxidation products also. For a correct determination of the total concentration of UDMH in soil, it is necessary to consider the simultaneous presence of active products of its transformation that are capable of hydrolysis back to the parent compound, such as formic acid 1,1-dimethylhydrazide. A comparative study was performed exploring the methods detailed in the literature for sample preparation. This was to inform select conditions for the quantitative extraction of UDMH that was bonded by various mechanisms to organic and mineral fractions

of soil and formic acid 1,1-dimethylhydrazide (one of the most common active transformation products) [451]. It was found that the steam distillation with a 40% NaOH solution with an addition of Na<sub>2</sub>S enabled the quantitative recovery of UDMH and formic acid 1,1-dimethylhydrazide from soils of all types and the determination of the maximum original concentration of UDMH in the analysis of real samples of contaminated soils.

Testing different methods for sample extraction and chromatographic determination of mobile forms of UDMH and NDMA for the analysis of peaty boggy soils (typical for the European North of the Russian Federation where spent launch vehicle stages might have impacted the environment) showed that within a 3-d period after UDMH penetration into the soil, no more than 15% of its initial content could be extracted [452]. A large fraction of UDMH can be extracted from peat by steam distillation in the presence of a 40% solution of sodium hydroxide.

In addition to the analysis of air samples, furaldehyde derivatization has also been successfully used for the analysis of hydrazine and UDMH contamination in ground water [360]. Separation was seen on 10% OV-101 on Chromosorb WHP 80/100 mesh-packed glass columns. Detection was conducted using a thermionic specific detector (TSD) or MS detector. The detection limit was ca. 36 ppb for UDMH. This method does not apply to MMH, because of incomplete derivatization and the instability of the derivative. It is advisable to use only freshly distilled 2-furaldehyde as the reagent and prepare the dilute aqueous solution fresh daily (2 mL of redistilled furaldehyde diluted to 50 mL with 0.5 M sodium acetate solution as a buffer).

SPME was very effective in extracting UDMH transformation products from soil samples contaminated with rocket fuel. The use of SPME resulted in high sensitivity, speed, and modest labor consumption due to automation, and it was simple to use. It was shown that water addition to soil leads to a significant decrease in the recovery of almost all target transformation products of UDMH. The use of SPME for sampling and sample preparation resulted in the detection of 21 new compounds that are relevant to the UDMH transformation in soils [453].

UDMH transformation products that can be detected by GC or GC/MS include FDMH [454] and MTA [455]. A wide range of transformation products of UDMH in contaminated soil and water were analyzed and identified using gas chromatographic methods [456, 457]. A review of all data on the transformation products of UDMH, including their identification, quantitative determination, distribution, and fate in the environment, listed the analytical methods for the determination of these compounds in the environmental samples [458]. This included the results of the identification of UDMH transformation products in soil samples collected from three sites where the first stages from space launch vehicles had impacted the ground.

A highly sensitive GC-tandem MS method was developed for the simultaneous determination of eight major products of oxidative transformation of UDMH in soil and water, namely formaldehyde dimethyl-hydrazone, acetaldehyde dimethylhydrazone, 2-furaldehyde dimethylhydrazone, 1,1,4,4-tetramethyl-2-tetrazene, *N,N*-dimeth-

ylformamide, NDMA, MTA, and 1-formyl-2,2-dimethylhydrazine [459]. The detection limits were in the range of 0.3–2.3 ng/mL, which was one to two orders of magnitude lower than those for the traditional GC/MS method. The developed approaches were tested during the analysis of real samples using the surface water of a peaty swamp with high contents of organic substances. These samples were collected at places of impact during the first stages from space launch vehicles. *N,N*-dimethylformamide and MTA were predominant among the detected UDMH transformation products in natural waters.

One of the more durable UDMH degradation products is MTA, which can be analyzed by GC-MS [460]. Quantitative analysis of trace concentrations of UDMH transformation products in water requires very sensitive analytical instrumentation and tedious sample preparation. A simple and automated method for sensitive quantification of UDMH transformation products in water was developed using headspace SPME in combination with GC-MS and GC-MS/MS [461]. This method is based on the extraction of analytes from the gas phase above samples by a micro-polymer coating followed by thermal desorption of analytes in a GC inlet. Extraction by 85  $\mu$ m Carboxen/polydimethylsiloxane fiber at 323 K (50 °C) over 60 minutes provided the best combination of sensitivity and precision. Detection limits of twelve analytes using GC-MS/MS with chemical ionization were about 10 ng/L. This method is simpler, automated, provide lower detection limits, and covers more UDMH transformation products than other methods. The method was recommended for assessing the water quality in areas affected by rocket launch activities.

Micro-analysis of UDMH in water is possible using GC, HPLC, or IC [462]. A new spectrophotometric method for determining trace amounts of UDMH was developed based on UDMH possessing some retarding activity to the rate of oxidation of methyl orange by potassium bromate in an  $\text{H}_2\text{SO}_4$  medium [463]. The linear range was 0.20–0.08  $\mu\text{g/mL}$  and the detection limit was  $1.3 \times 10^{-2} \mu\text{g/mL}$ . This method was used with good results to determine trace quantities of UDMH in water samples and it offered simplicity, high sensitivity, and good stability.

#### 1.4.11.9 Analysis of NDMA in the Presence of UDMH

NDMA is an oxidation product of UDMH. It can also be an intermediate in the manufacturing of UDMH if carried over from the production process. Several extremely sensitive analysis methods have been developed to perform trace analysis on this potential carcinogen in liquid and in the air. Atmospheric sampling for NDMA performed by the Environmental Protection Agency (EPA) in Baltimore in 1975 downwind of a UDMH manufacturing plant was done using cryogenic samplers. Air samples were collected cryogenically, extracted with dichloromethane, concentrated, and then analyzed on a GC with an *N*-nitroso compound-specific thermal energy analyzer [464–466]. The NDMA levels were found to vary between 16 to 760 ng/m<sup>3</sup>. The thermal energy analyzer decomposes the *N*-nitroso compound on a catalyst into an amino radical and an NO radical. The amino radical is trapped in a cold trap at 153 K, which the nitroso

radical passes unchanged. The NO is then reacted with ozone, forming electronically excited nitrogen dioxide. The excited  $^*\text{NO}_2$  relaxes to its ground state with the emission of nearly monochromatic light in the IR region of the spectrum. The IR emission is recorded on a photomultiplier. The intensity of the emission is proportional to the number of NO radicals present. NDMA levels observed in the air of inhabited suburbs of Baltimore, MD, varied between 16 and 760 ng/m<sup>3</sup>, causing a significant amount of public concern about the potential health effects of this air pollutant. In a few instances, *N*-nitrosodiethylamine was also detected. In a simultaneous effort, two different sampling and analysis methods were used, essentially producing identical results [467]. One group sampled the air in two consecutive cold traps cooled to 195 K, extracted the traps with dichloromethane, concentrated the extracts, and injected the sample into a GC with a thermal energy analyzer. The other group concentrated organic vapors from ambient air on a pre-conditioned Tenax-GC cartridge that was then desorbed in a laboratory and analyzed using capillary GLC in conjunction with a mass spectrometer. The highest value of 32000 to 36000 ng/m<sup>3</sup> was observed adjacent to the UDMH facility. However, NDMA was also found in the air in the vicinity of a methylamine-producing plant in Belle, WV. In this instance, atmospheric nitrosation must have led to the formation of NDMA. Consequently, any fish processing plant might be a suspected source of atmospheric NDMA. By comparison, *N*-nitroso compounds were not found in the air of urban centers in Philadelphia, PA, Wilmington, DE, or Waltham, MA. In addition to the cryogenic sampling and adsorption on Tenax tubes, air samples have also been taken by bubbling the air through an impinger with dilute alkali [468, 469].

A comparison of analytical methods for the measurement of NDMA in UDMH-enriched atmospheres in animal exposure chambers included three different sampling methods: **(1)** three-stage cryogenic sampling with analysis by coupled GC-MS; **(2)** NDMA concentration on Tenax-GC cartridges with analysis by GC-MS after applying the method used by Pellizzari et al. (1976) [470], and **(3)** impinger sampling with analysis using a thermal energy analyzer (TEA) and employing a method used by Fine and Rounbehler [471].

An improved atmospheric sampling technique for NDMA and UDMH has been developed; it aspirates air through sorbent tubes filled with Tenax-GX (a 2,6-diphenyl-*p*-phenylene oxide polymer) [472]. The adsorbed contaminants were then desorbed and injected into a GC-MS data system where individual GC peaks could be identified by their MS fractionation pattern. This method can detect 0.17 µg NDMA in a 240-L air sample (21 ppb).

Astounding detection sensitivity for NDMA has been developed using a GC-MS with methane chemical ionization and single-ion ( $m/e$  75) monitoring [473, 474]. This method can detect 50 pg of NDMA per injection.

The EPA's Method 607 for the analysis of NDMA in treated UDMH wastewater was modified to meet the requirements of ambient water quality criteria (as set by the EPA), which is 0.0014 parts per billion (ppb) [475]. It was concluded that a target treatment

level of 0.0014 ppb for NDMA was realistically unachievable given the state of analytical technology available at that time. However, the technology available in the 1990s could yield reliable data in the  $10^{-4}$  to  $10^{-6}$  cancer risk factor range between 0.140 and 0.0014 ppb of NDMA.

NDMA, a degradation compound of UDMH in UDMH-containing wastewater, can be analyzed using GC/MS in the selected ion monitoring mode [476]. The wastewater sample was pre-treated using steam distillation, extraction with dichloromethane, and concentration by blowing with nitrogen. The linear relationship between the peak area and concentration of NDMA was obtained in the range of 0.31–1.54 mg/L with a detection limit of 2 µg/L. Tests for recovery and precision of this method were made by adding 2.016 µg or 10.08 µg of NDMA to 100 mL of distilled water. The recovery was 88.8 and 89.3%.

#### 1.4.11.10 Analysis of UDMH Vapors in Ambient Air

Analytical methods for detecting and quantifying UDMH vapors in the air can be either grab samples (spot analysis) or continuous direct-readout instruments with an alarm function when a certain threshold concentration is exceeded. Many different analysis methods have been developed for this purpose [477].

##### Analysis of UDMH Vapor with Grab Samples-Active Sampling

Active sampling devices require a pump and a flow meter to force the air through the absorbent material or to bubble the air through an impinger filled with dilute acid.

NDMA is either an oxidation product of UDMH or an intermediate in the manufacturing of UDMH. Several extremely sensitive analysis methods have been developed to perform trace analysis on this suspected carcinogen.

An improved atmospheric sampling technique for NDMA and UDMH aspirates air through sorbent tubes filled with Tenax-GX (a 2,6-diphenyl-*p*-phenylene oxide polymer) [472]. The adsorbed contaminants were then desorbed and injected into a GC-MS data system where individual GC peaks could be identified by their MS fractionation pattern. This method can detect 0.17 µg NDMA in a 240-L air sample (21 ppb).

##### Analysis of UDMH Vapor in Air-Passive Sampling

Passive sampling devices in the shape of lapel-worn badges like those used in radiation dosimetry can absorb UDMH vapors and either cause a color change for immediate indication or can be extracted at the end of the work shift to obtain a cumulative reading for the entire duration of exposure. The devices depend on the diffusion and natural convection of the air.

A portable system for the detection of low concentrations of UDMH in air was based upon the change of electrical resistivity of thin metal films when exposed to propellant vapors [478]. Sensitized gold metal films coated with appropriate salts were found to be optimum for UDMH. UDMH could be monitored over the range of 0.1 to 50 ppm with a standard deviation of about 20%. The effects of temperature over the

range of 323 to 363 K (50 to 90°C) and of humidity from 10 to 90% R.H. on the response characteristics of the thin film sensors were found to be significant but within the tolerance limits. A portable breadboard direct readout instrument was designed and fabricated for use with the sensors to form an integrated detection system for personal protection.

### Continuous Analysis of UDMH Vapor in Ambient Air

During the 1960s when UDMH and Aerozine-50 were introduced as fuels in various missile and launch vehicle systems, there was an acute need for air monitors that would both provide an instant readout for continuous recording and also sound an alarm if an allowable threshold concentration was exceeded. For the installation in Titan-2 missile silos, the difficulty was that the sensors had to be able to discriminate and/or operate in spite of the potential simultaneous presence of nitrogen dioxide from a leak of the oxidizer in the missile.

Infrared spectrophotometric instruments can be tuned to specific wavelengths where absorption bands for propellant vapors are known to exist. These instruments can detect more than one propellant at a time [479].

A variety of instruments were evaluated for this purpose but not all led to reliable and reproducible results [480]. Calibration and maintenance of these instruments became a time-consuming operation.

Multiple ("frustrated") internal reflection is a method to achieve very long-path-lengths in a cell with manageable (if not even portable) external dimensions. One such instrument detected UDMH at the 0.5 ppm level [481]. If UDMH vapor or vapor from other airborne hydrazines condenses on the surfaces of a cooled KRS-5 crystal in an IR spectrophotometer, multiple internal reflections allow the measurement of IR spectra of very thin films of condensate. At 12.4  $\mu\text{m}$ , UDMH has a strong and specific absorption band that is suitable for the detection of traces of UDMH (down to 5 ppm) in air [482]. There have been attempts to increase the sensitivity by coating the crystal with an absorbent film of low volatility (naphthyl isocyanate). The sensitivity was increased by two orders of magnitude; nonetheless, the signal was persistent after the first alarm and the crystal had to be cleaned and recoated to restore the stand-by operating condition.

During preliminary testing of a conductive polymer-based hydrazine sensor, the sensor showed promise as a dosimeter with the ability to detect hydrazine and UDMH at levels well below the threshold limit value (TLV) of 10 parts per billion (ppb) [483–485]. The original sensor demonstrated a minimum detectable dose of approximately one part per billion  $\times$  hour (ppb  $\times$  h) and a saturation dose of approximately 250 ppb  $\times$  h in dry conditions, offering adequate coverage of the TLV limit of 80 ppb  $\times$  h (eight hours at 10 ppb).

Electrically conductive polyaniline-coated fibers have been prepared by polymerization of aniline on surfaces of commercial polymer fibers in the presence of an oxidizing agent and used for the detection of UDMH vapors in the air [486]. The changes in

resistance of a polyaniline-coated fiber sensor were investigated and related to coating conditions. The morphology of the conducting film on the surface of the fibers was examined by SEM. The sensing behavior of a polyaniline-coated fiber sensor in the presence of other volatile organic compounds was studied experimentally. A polyaniline-coated fiber sensor demonstrated good sensitivity for UDMH and good reproducibility when re-used.

### Calibration of UDMH Vapor Detectors

Calibration of vapor detectors must be repeated frequently; the accuracy of the instruments are only as good as the accuracy of their calibration. Permeation tubes are commonly used to generate a constant flow of vapors in the air, followed by cascading dilution circuits to bring the original concentration of vapor from the temperature-controlled permeation device down to the sensitivity range of the instruments.

A study of the effect of temperature on the permeation rate for UDMH, MMH, and Hz permeation tubes showed that the variation of logarithm of permeation rate with the temperature is linear between 298 and 313 K (25–40 °C) [487]. The changes of their permeation rates were 0.65, 0.6, and 0.76% for UDMH, MMH, and Hz, respectively, when the temperature fluctuation was only 0.1 °C. The permeation rate slowly returned to the original value after brief and small temperature excursions.

A UDMH permeation tube with a permeation rate of 0.5–30.5 µg/min was prepared with high-purity UDMH as the raw material [488]. The instrument was monitored for homogeneity and stability for 13 months.

A dynamic hydrazine vapor generator, in which high-purity GN<sub>2</sub> served as the diluent gas, can develop standard hydrazine vapor concentrations using accurate amounts of hydrazine liquid injected continuously into the gas stream and an evaporator using a metering pump [489]. This equipment was able to make standard hydrazine vapor mixtures from 0.1–100 volume ppm under certain conditions.

The operating principle of UDMH vapor dynamic gas mixing equipment was examined for linearity, repeatability, and stability of the equipment [490]. The dynamic gas mixing equipment can generate hydrazine vapor mixtures of 0.1–100 ppm under carefully controlled conditions such as constant surrounding temperature, regular flow, and temperature of diluent gas.

#### 1.4.11.11 Analysis of UDMH in Food Stuff

Several decades ago, the use of succinic acid dimethylhydrazide, daminozide, and “Alar®” on apple trees in orchards and the presence of UDMH as a hydrolysis product had created a controversy between environmentalists and apple growers about the safe levels of residual daminozide and UDMH on fruit. Therefore, methods for the analysis of hydrazine residues on food crops had to be standardized. The US National Bureau of Standards has compiled a summary of recommended methods for the analysis of hydrazines on crops [491].

#### 1.4.11.12 Analysis of UDMH Decomposition Products from a Gas Generator

UDMH can be used as a monopropellant and gas generant, although the exhaust is very dirty. UDMH gas generators have been used to run turbines that drive the propellant pumps in missiles and launch vehicles that used NTO/UDMH. These gas generators usually are started with a hypergolic oxidizer and then operate extremely fuel-rich.

Besides the analysis of alkylhydrazines in various matrices, sometimes chemists need to analyze UDMH decomposition products consisting mostly of methane, ammonia, nitrogen, and hydrogen, depending on the degree of ammonia and methane dissociation. The ammonia dissociation is often a design variable in the design of rocket engines (see *Encyclopedia of Monopropellants*). The thermal decomposition products of UDMH in a thermal bed gas generator constitute a very unpleasant mixture of gases that are difficult to analyze. IR analysis showed the mixture to contain ammonia, methane, hydrogen cyanide, and small amounts of ethane, ethylene, and propane but no alkylamines [492]. The ammonia concentration could be calculated from the absorbances at 6.1, 10.31, and 10.7  $\mu\text{m}$ . A combination of absorptions at 3.15, 3.28, 3.34, and 10.50  $\mu\text{m}$  was used to mathematically derive the methane, ethane, ethylene, and propane concentrations. The hydrogen cyanide content was found directly from the absorption at 13.77 to 14.03  $\mu\text{m}$ .

#### 1.4.12 Salts of Unsymmetrical Dimethylhydrazine

Dimethylhydrazines form salts with strong acids. The salt of major concern is *N,N*-dimethylhydrazinium(1+) nitrate,  $[(\text{H}_3\text{C})_2\text{NHNH}_2]^+[\text{NO}_3]^-$ ,  $(\text{H}_3\text{C})_2\text{NHNH}_2\text{NO}_3$ , UDMHN,  $\text{C}_2\text{H}_5\text{N}_3\text{O}_3$ ,  $M = 123.11 \text{ g/mol}$ , 8.1228 mol/kg. This sometimes forms inadvertently from residual bipropellants in NTO/UDMH thrusters from the dribble volume after the engine has shut down. Under adverse conditions, the salt may accumulate in the engine and explode the next time the engine is operated resulting in severe pressure spikes. It may also fog up nearby solar panels or camera windows. An IR spectrum of dimethylhydrazinium(1+) nitrate is shown in Figure 17.

The heats of combustion of *N,N*-dimethylhydrazinium nitrate,  $[(\text{H}_3\text{C})_2\text{NHNH}_2][\text{NO}_3]$  were determined experimentally and calculated thermodynamically [494]. The agreement between the experimental and theoretical values (in parentheses) was very satisfactory: +1824 (+1739) kJ/mol = 14820 (14125) kJ/kg = 3542 (3376) kcal/kg.

UDMHN crystals are deliquescent and hygroscopic. Water that has been co-ordinated to the molecules cannot be removed in a vacuum, and heating under a vacuum results in decomposition. Longer storage under atmospheric conditions leads to yellow or even brown liquids. Dry 1,1-dimethylhydrazinium nitrate forms orthorhombic crystals, space group  $Pna2_1$  with the unit cell parameters of  $a = 14.0388(4) \text{ \AA}$ ,  $b = 5.6493(1) \text{ \AA}$ ,  $c = 7.6026(2) \text{ \AA}$ ,  $\beta = 90^\circ$ ,  $V = 602.96(3) \text{ \AA}^3$ ,  $Z = 4$ , and  $\rho_{\text{XRD}} = 1.35620(7) \text{ g/cm}^3$  [495]. The arrangement of dimethylhydrazinium ions and nitrate ions in the crystal lattice has been illustrated in an Oak Ridge Thermal

**Figure 17:** Infrared spectrum of dimethylhydrazinium(1+) nitrate in a KBr pellet. (Reproduced and modified from [493].)

Ellipsoid Plot (ORTEP) plot together with bond lengths. UDMHN demonstrated poor sensitivity towards shock or friction. No detonation was observed in the drop hammer impact sensitivity test. Also, no detonation was observed when grinding the compounds in a mortar. UDMHN was insensitive to an electric discharge of about 20 kV. Fast heating with a Bunsen burner resulted in melting, and at higher temperatures, in a vigorous decomposition under gas evolution. Slow heating led to a slow decomposition at temperatures higher than 333 K (60 °C).

*N,N*-Dimethylhydrazinium dicyanamidate and nitrocyanamidate ionic liquids were prepared by quaternization of UDMH with alkyl halides, followed by metathetical reactions with silver dicyanamidate or silver nitrocyanamidate [496]. These liquids are hypergolic with RFNA. Other ionic liquids were formed from UDMH and arylheteroacetic acids [497].

1,1-Dimethylhydrazinium azide,  $[(\text{H}_3\text{C})_2\text{N}^+\text{H}-\text{NH}_2][\text{N}_3]^-$ , UDMHAz, is a potential by-product of a partial reaction of UDMH with NTO. 1,1-Dimethylhydrazinium azide was prepared from UDMH and  $\text{HN}_3$  in  $\text{CH}_2\text{Cl}_2$  solution at 253 K (−20 °C). The resulting white precipitate was filtered off, dried, and stored in the freezer at 255 K (−18 °C). The crystals with a melting point of 311 K (38 °C) were characterized by elemental analysis, multi-nuclear NMR ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ,  $^{15}\text{N}$ ), and vibrational spectroscopy (IR, Raman) [498]. The structure of the monoclinic crystals was determined by low-temperature (173 K) single-crystal XRD analysis and the unit cell parameters were  $a = 8.5411(2)$  Å,  $b = 7.0415(2)$  Å,  $c = 10.0878(1)$  Å,  $\alpha = \gamma = 90^\circ$ ,  $\beta = 108.321^\circ$ , space group  $P2(1)/n$ ,  $Z = 4$ , and  $\rho_{\text{XRD}} = 1.205 \text{ g/cm}^3$ . Preliminary studies exploring the safety properties of UDMHAz revealed low impact sensitivity, electrostatic sensitivity, thermal sensitivity, and some friction sensitivity. Similar tests were performed for methylhydrazinium azide [499].

The hydrogen-bonded dimethylhydrazinium and azide ions form layers. The methyl groups of the dimethylhydrazinium ions are above and below these layers

so that two methyl groups are between each layer. Dimethylhydrazinium(1+) azide was found to have almost no sensitivity towards shock or friction. No detonation was observed after dropping a weight of 5 kg from 50 cm onto this compound, nor was any detonation observed when grinding the compound in a mortar. The  $\text{HN}_3$  salts of MMH or UDMH did not explode when heated with a heating rate of about  $10^\circ\text{C}/\text{min}$ . They sublimed away from the heat source. An explosion can only be started by a strong heat source, such as with a hot metal plate or a Bunsen burner. The more methyl groups that are attached to the hydrazinium ion, the fiercer the explosion gets. Methylhydrazinium azide and *N,N*-dimethylhydrazinium azide demonstrated the same properties, while trimethyl- and tetramethylhydrazinium azide had much bigger explosions.

Methylhydrazinium azides are all sensitive to oxidation. The oxidation is faster in compounds where more methyl groups are present. Methylhydrazinium azide is hygroscopic but can be stored in air for several minutes before a color change occurs, while the liquid  $\text{HN}_3$  salts turn brown immediately and form black residues in minutes.

Alkylhydrazinium azides were prepared by reacting the anhydrous alkylhydrazines with a solution of hydrazoic acid in ether [500, 501]. As more and more methyl groups are attached to hydrazine, the melting point of the  $\text{HN}_3$  salt decreases. Some are liquids at room temperature. The volatility of the compound also increases. With more methyl groups the elimination of  $\text{HN}_3$  from the molecule gets easier. Tetramethylhydrazinium azide will eliminate  $\text{HN}_3$  at room temperature. If a permethylated nitrogen atom is present, the molecule can no longer eliminate  $\text{HN}_3$ . Alkylhydrazinium azides with quaternized and permethylated nitrogen atoms can be synthesized via anion exchange from the corresponding alkylhydrazinium iodide with silver azide.

The reaction of 1,1-dimethylhydrazine with a solution of HCl in  $\text{Et}_2\text{O}$  results in the formation of an anhydrous salt  $(\text{H}_3\text{C})_2\text{N}(\text{H}^+)\text{NH}_2\cdot\text{Cl}^-$  in the form of needle-shaped, light orange, monoclinic crystals, space group  $P2_1/n$  [502]. The crystal structure, determined by XRD analysis, consists of two independent  $[(\text{H}_3\text{C})_2\text{NHNH}_2]^+$  cations and two  $\text{Cl}^-$  anions that are connected via hydrogen bonds. Unit cell parameters were  $a = 9.7305(9) \text{ \AA}$ ,  $b = 10.5319(10) \text{ \AA}$ ,  $c = 10.4759(10) \text{ \AA}$ ,  $T = 193 \text{ K}$ ,  $\beta = 90.475(11)^\circ$ ,  $V = 1073.54(18) \text{ \AA}^3$ ,  $Z = 8$ , and  $\rho_{\text{XRD}} = 1.195 \text{ g/cm}^3$ .

Most organic amines and hydrazines can be isolated and characterized in the form of their poorly soluble and well-crystallized picrate salts. UDMH (0.02 mol) was slowly added to a solution of picric acid (0.02 mol) in 30 mL ethanol at room temperature [503]. Single monoclinic crystals, space group  $C2/c$ , that are suitable for XRD structure analysis were obtained by slowly evaporating a distilled water solution of UDMH picrate at room temperature. The unit cell parameters were  $a = 14.2038(17) \text{ \AA}$ ,  $b = 8.1932(10) \text{ \AA}$ ,  $c = 21.233(3) \text{ \AA}$ ,  $T = 296 \text{ K}$ ,  $\beta = 98.298(2)^\circ$ ,  $V = 2445.1(5) \text{ \AA}^3$ ,  $Z = 8$ , and  $\rho_{\text{XRD}} = 1.571 \text{ g/m}^3$ .

UDMH oxalate is poorly soluble in water and well crystallized. It can be used for the separation of UDMH and for fission product separation in nuclear fuel element

reprocessing [504]. It is known that hydrazinium nitrate is used for nuclear fuel element reprocessing in the PUREX process, however, it is not known why UDMH oxalate should have an advantage over hydrazinium salts in that application. UDMH oxalate has been characterized and tested for fuel element cladding (Zr) separation from the fission products [505].

The crystal structures of 1,1-dimethylhydrazinium(1+) bromide,  $\text{C}_2\text{H}_9\text{N}_2^+ \cdot \text{Br}^-$ , (**I**), and 2,2-dimethylhydrazinium(1+) dihydrogen phosphite,  $\text{C}_2\text{H}_9\text{N}_2^+ \cdot \text{H}_2\text{PO}_3^-$ , (**II**) were determined by XRD [506]. In (**I**), the cation is protonated at the methylated N atom.  $\text{N}-\text{H} \cdots \text{Br}$  hydrogen bonds generate [010] chains in the crystal. In (**II**), the cation is protonated at the terminal N atom. The cation-to-anion  $\text{N}-\text{H} \cdots \text{O}$  and anion-to-anion  $\text{O}-\text{H}-\text{O}$  hydrogen bonds generate (001) layers.

## 1.5 Materials of Construction for Unsymmetrical Dimethylhydrazine

Experimental methods for determining the compatibility of hydrazine(s) fuels with materials of construction have already been detailed in *Encyclopedia of Liquid Fuels* within the chapter “Hydrazine.” Methods that have been successfully used for hydrazine  $\text{N}_2\text{H}_4$  can equally well be used for determining material compatibility with UDMH or MMH.

Quite often, data may be available for one of the three propellant hydrazines but not for the hydrazine of interest. To a limited extent, it is possible to extrapolate metal compatibility data from one hydrazine to another. For metallic materials, extrapolation is easier than for non-metals. Metals found to be compatible with hydrazine will most likely also be compatible with MMH and UDMH. Similarly, metals found to be compatible with MMH will most likely also be compatible with UDMH. Polymeric organic materials are more likely to swell in UDMH than in MMH or hydrazine.

### 1.5.1 UDMH Compatibility with Metals

Corrosion rate determinations were made on several metals for 28 d at 303 K (30 °C = 86 °F) or for 7 d at 436 K (63 °C = 146 °F), which is the UDMH reflux temperature [507]. The metals shown to be satisfactory in these tests were the 300-series stainless steels, CRES-416, CRES-422, CRES-A286, CRES-4130, 15-7PH, and 17-7PH. Hastelloys-B, -C, -F, and -X and commercially pure titanium. Its alloys, C120AV and B120VCA, were also acceptable. Elastomers and plastics that were compatible with UDMH included butyl rubbers, Hydropol-T, Teflon, unplasticized Kel-F, and polyethylene. Corrosion rates in all these metals were generally  $7.6 \mu\text{m/yr}$  (0.3 mil/yr) or less. Aluminum 1260-H14 was strongly attacked by UDMH-water mixtures but not by anhydrous UDMH. Components for UDMH production facilities were initially made from stainless steel. However, as time passed and more experience was gained and the Westvaco plant for the production of UDMH was enlarged, storage and shipping containers were changed

to mild steel (e.g., mild steel ICC-17C drums). Unsymmetrical dimethylhydrazine was stored without corrosion for 18–25 months in mild steel 55-gal drums in Baltimore, MD. The UDMH analyzed after this storage was still clear and colorless. Several drums were cut open and showed no internal corrosion. Both UDMH and UDMH-JP4 mixtures (JP-X and M-3) have been stored for several years in missile propellant tanks, such as aluminum 6061-T6 tanks in the BOMARC, VANGUARD-ABLE, THOR-ABLE, and NIKE-AJAX; UDMH-amine mixtures for the JUPITER-C satellite launcher were transported in Al-5052 tank cars. Aluminum-6066-T4 was used for BULLPUP, and other aluminum alloys were used for AGENA tanks. Compatibility data for UDMH or Aerozine-50 are summarized in Table 15.

**Table 15:** Literature references regarding the compatibility of metals with UDMH and Aerozine-50.

| Material    | Gas evolution | Corrosion rates |       | Stress-corrosion fracture |                 | Weight change |
|-------------|---------------|-----------------|-------|---------------------------|-----------------|---------------|
|             | Ae-50         | UDMH            | Ae-50 | UDMH                      | Ae-50           | UDMH          |

While searching for materials for advanced spacecraft valves, several hundred literature references on 21 different propellants that were in use as of 1967, or were anticipated to be used within the next ten years (including UDMH), were assembled [515]. However, the report by Salvinski, Howell and Lee (1967) on pages 1–24 through 1–27 only lists compatibility materials and temperatures and not the duration of immersion [515]. Similar data are on pages 3–21 through 3–25 of [516].

One indication of material incompatibility is gas evolution. There are many UDMH compatibility tests where gas evolution rates were measured. One example is shown in Figure 18, although this example, unfortunately, does not include the most common

stainless steel, CRES-304. The graph demonstrates that rusted steel is much worse than clean steel and that adding surface area in the form of shavings also increases the rate of gas evolution. Similar data are available for MMH. The source from which this second-hand information was taken failed to provide the surface:volume ratio and ullage ratio for this type of test. The original source of the data was [102]. This report was confidential and is difficult to obtain (see also [517]).

**Figure 18:** Pressure rise during UDMH storage at 344 K (71°C). (Reproduced and modified from [95].)

### 1.5.2 Stress-Corrosion Cracking in UDMH

UDMH prepared using the Raschig or chloramine process may contain varying amounts of chloride as a contaminant. Residual cleaning fluids such as Freon-TF may react with UDMH, leading to a release of chloride. Both sources of chloride may lead to stress-corrosion cracking of tankage materials holding UDMH. Stress-corrosion cracking tests of Al-2014-T6, CRES-304L, and Ti-6Al-4V in UDMH containing varying levels of chloride ion up to 100 ppm revealed that even the highest  $\text{Cl}^-$  level tested had no adverse effect on the sustained load crack growth of any of the three alloys [509]. This was of particular significance for the titanium alloy, which (in other fluids) is sensitive to chloride contaminations of the order of 1 ppm. Since no effects were observed at 100 ppm  $\text{Cl}^-$  in UDMH, a specification limit maximum of 30 ppm for  $\text{Cl}^-$  in UDMH seemed to provide a sufficient margin for safety. Part-through cracked or surface-cracked specimens loaded in uniaxial tension were used because they simulate real cracks in tanks under internal pressure load conditions. The specimens were notched in the center of each test section prior to the test. From this notch, an initial crack was started by cyclically stressing the notch in bending. Only then was the UDMH exposure commenced to study additional crack propagation.

The steel alloy AISI 4130 – a high-strength, low-alloy material – was selected as a test material because it is known to be highly susceptible to stress corrosion in several corrosive fluids [510]. Although AISI 4130 is generally not recommended for an-

hydrous hydrazine service because it rusts too easily, it is compatible with MMH and UDMH, based on static compatibility test results. In addition to 4130, for which stress corrosion in contaminated hydrazines was not unexpected, several other alloys, stainless steel 410, titanium-6Al-4V, aluminum-6061-T6, and Inconel-718 were also tested for stress-corrosion susceptibility. These alloys are more frequently used in components where they are wetted by UDMH. The metal specimens were pre-cracked by fatiguing, and then a tapered plug was inserted to load the stressed area. The plug was not immersed in the liquid. The liquid level reached only to and above the pre-cracked area. With 4130, no crack extension occurred in UDMH up to at least 2000 h. MMH caused growth after 500 h and hydrazine caused growth after about 60 h. Aerozine had about the same effect on 4130 as straight hydrazine. Methylhydrazine was more active than UDMH. The alloys mentioned can be ranked in the following order of decreasing susceptibility to stress corrosion: 4130 steel, CRES-410, Inconel-718, Ti-6Al-4V, and Al-6061-T6. In the tests conducted at NASA Ames, no crack growth was observed with Ti-6Al-4V, but other investigators using different sample geometries observed stress-corrosion cracking of this material in Aerozine-50 [513, 514].

Several high-toughness steels, including T-1, HY-140, HP-9-4-20, and 18Ni(200) maraging steel (that do stress corrode and crack in seawater), did not show stress corrosion in (presumably pure) UDMH at 322 K ( $49^{\circ}\text{C} = 120^{\circ}\text{F}$ ) [518]. Aluminum alloy LD10 double cantilever beam specimens were corroded under the conditions of UDMH,  $\text{N}_2\text{O}_4$ , or 3.5% NaCl aqueous solution immersion [519]. There were no stress-corrosion phenomena observed in UDMH.

### 1.5.3 UDMH Compatibility with Non-Metallic Materials

Polymers found to be compatible with MMH will most likely also be compatible with UDMH and hydrazine. Similarly, polymers known to be compatible with hydrazine may dissolve or swell in either MMH or UDMH.

The influence of the contact time of UDMH with styrene-butadiene rubber (SBR) on the tensile properties of SBR under certain temperature conditions was studied through immersion aging tests [520]. The results demonstrated that change rates of the tensile strength and elongation at break of SBR after soaking decrease logarithmically with prolongation of the soaking time. A major reason for the decrease of tensile properties of SBR is swelling. UDMH may leach plasticizers, such as phthalates and phosphate esters, from non-metallic materials of construction it comes into contact with [521].

### 1.5.4 Tubing for UDMH Vapor Samplers

The selection of materials for the propellant vapor manifold for remote sampling of UDMH vapors in rocket launch sites or in animal inhalation toxicity test chambers required a special study. There was not much concern about UDMH inadvertently destroying the tubing; instead, concern was raised about low vapor concentration

samples hanging up in the tubing on their way from the sampling location to a central analyzer. The plastics tested for UDMH sampling included polyethylene-lined ethyl vinyl acetate, high-density polyethylene (HDPE), polypropylene, Teflon TFE (polytetrafluoroethylene), Teflon FEP (polytetrafluoroethylene- polyhexafluoropropylene), and Teflon PFA (polytetrafluoroethylene-perfluoropropyl vinyl ether). Sample lengths of 23 and 61 m were investigated for their effect on performance [522, 523]. All tubing performed about equal with regard to sample retention, response time, and ease of cleanout with methanol. While the polyethylene-lined ethyl vinyl acetate tubing appeared most suitable for MMH, Teflon FEP, and HDPE performed best for UDMH sampling.

Unrecognized vapor loss by permeation and oxidation in incompatible plastic tubing has thrown some doubt on the validity of animal inhalation toxicity tests with hydrazine(s). These test data were later used as a reason for lowering TLV-TWA values in the 1990s without further examination of their accuracy.

### 1.5.5 Storage Tests with UDMH Blends

MAF-4 is a mixture of 60 UDMH/40 DETA. MAF-4 was previously known as “U-DETA” and “Hydyne.” The storability of MAF-4 in pre-packaged missile tanks was critically examined after an explosion caused by the adjacent IRFNA oxidizer tank when it was stored in a hot climate [524].

## 1.6 Handling of UDMH

### 1.6.1 Storage, Transportation, and Handling of UDMH

There are numerous reports and handbooks regarding the storage and handling of UDMH, usually in combination with details of using its most important propellant blend, Aerozine-50 (see also [525, 526]). Hydrazine, MMH, and UDMH were once shipped (and are sometimes still shipped) in containers of the type listed in *Encyclopedia of Liquid Fuels* within the chapter titled “Hydrazine” (Table 73). The US Army used trailer tank trucks to move UDMH and MAF fuels to the front lines to service the LANCE and BULLPUP missiles [527–529].

### 1.6.2 Leak Detection of UDMH

UDMH vapors from leaks in storage areas can be detected by the same active instruments that are also used to monitor UDMH concentrations in the air within workspaces where personnel might be exposed.

If UDMH storage systems are painted with a paint that changes color with UDMH exposure, propellant leaks can be quickly located, and corrective action can be taken. This leak detection method also works in areas where no electricity is available.

Lacquers and enamels were developed that undergo vivid color changes upon being exposed to propellants containing substituted hydrazines, nitric acids, or elemental halogens [530].

### 1.6.3 UDMH Propellant Spills

#### 1.6.3.1 Accidental UDMH Spills

Despite all the care that is devoted to planning and conducting the storage and transfer of hydrazines, occasional spills may still occur. Several reports about spills of rocket propellants and poisoning accidents in the former USSR were mostly concerned with spills of the oxidizer, dinitrogen tetroxide, judging by the red color of the clouds that are often shown in the photo/video coverage of these events.

#### 1.6.3.2 Controlled Spill Tests

As part of the Titan-II development program, the USAF performed controlled deliberate spill tests with both  $N_2O_4$  and Aerozine-50, simulating a worst-case scenario [531]. Twenty model missile spills using total propellant quantities of 50 and 300 lb and two large-scale spills using total propellant quantities up to 1600 lb were made at Haystack Butte, Edwards AFB. The Titan II propellants,  $N_2O_4$  and Ae-50, were also spilled in quantities up to 2.5 lb of total propellant in a series of small-scale tests. A biological study of the impact on surrounding biota was performed on one large-scale test.

#### 1.6.3.3 Modeling of Atmospheric Dispersion of UDMH Vapors

Chapter “Hydrazine” in this *Encyclopedia of Liquid Fuels* contains a fairly detailed summary of studies and computer models for predicting the rate of evaporation and atmospheric dispersion of UDMH spills in addition to similar studies for hydrazine itself, MMH, Ae-50, and NTO. Only a few of these models include degradation of UDMH vapors by autoxidation, photolysis, or adsorption on aerosol particles in the air.

A computerized evaporation algorithm predicts the rate of evaporation from propellant spills as a function of soil temperature, solar insolation, air temperature, wind velocity, and spill dimension [532, 533]. The model allows for the absorption of water and carbon dioxide from the atmosphere into a liquid puddle that would slow the rate of evaporation. It will also provide a calculation of the amount of water required to dilute a spill below hazardous concentrations. In some instances, such as in massive Titan-III or Titan-IV launch failures, the toxic vapor/toxic aerosol plume is a mixture of solid propellant combustion products containing hydrogen chloride and aluminum oxide with the unreacted dinitrogen tetroxide and Aerozine-50 from the liquid stages. Modeling atmospheric diffusion of plumes of this nature is a very complex task [534, 535]. Some reactions continue to occur on the aluminum oxide particles while they disperse and descend.

Sample calculations for 200-L (drum), 20000-L (trailer), and 36000-L (rail car)  $N_2H_4$ , MMH, and UDMH spills at three different ambient temperatures (273, 288, and

303 K) showed that in the case of a 36000-L spill, the hazard corridor would reach 480 m downwind for hydrazine, 1380 m for MMH, and 680 m for UDMH. The rate of evaporation from a liquid pool is

$$\dot{m} = k_m \frac{P_v M A}{R T_p}$$

where  $\dot{m}$  is the mass flow (kg/h),  $k_m$ , the mass transfer coefficient (m/h),  $P_v$ , the vapor pressure (kPa),  $A$ , the spill area (m<sup>2</sup>),  $R$ , the universal gas constant (8.314 kPa m<sup>3</sup> kg<sup>-1</sup> mol<sup>-1</sup> K<sup>-1</sup>),  $M$ , the molecular weight, and  $T_p$  = temperature of pool (K). Allowances were made for composition changes in the remaining pool due to preferential evaporation of a more volatile constituent of a mixture, absorption of water from the atmosphere, and both absorption of and reaction with carbon dioxide from the atmosphere. The evaporation rates of UDMH and MMH for similar meteorological and spill conditions are 11 and three times that of hydrazine, respectively. A comparison of predicted and experimentally observed evaporation rates revealed good agreement for the first hour of the experiment.

The launch abort problem, such as for a Titan-III or Titan-IV launch mishap, is especially difficult because there are separate initial clouds of fuel and oxidizer with regions between them where fuel and oxidizer are mixing and reacting. Attempts were made to deal with this problem using a “multi-bin” approach, which treated the fuel and oxidizer and an interface as separate bins but kept the computation tractable [536]. The computer program was based on SURFACE CHEMKIN, a standard chemical kinetic subroutine package [537]. The model results showed that the outcome is highly dependent on initial conditions. For instance, a likely scenario for a Titan-IV accident will result in 24% of the initial oxidizer remaining, of which at least half is transformed into nitric acid. Two-percent of the initial fuel is expected to remain.

The determination of a hazard corridor following a hydrazine or UDMH spill involves two separate calculations [538, 539]. First, an estimate of the evaporation rate (“source strength”) must be calculated [540]. Then an atmospheric diffusion model must be employed to predict the downwind distance required to dilute that source strength to a concentration that is considered to be tolerable. Computer models are available that will predict the concentration-time profile of the vapor plume as the function of ten input parameters. Constants that are part of the equations have been determined for UDMH, MMH, hydrazine, and H-70.

Concentrations and the dispersion of UDMH vapor clouds formed by non-burning propellant that splashed onto the ground and evaporated then diffused after a launch failure of a liquid propellant launch vehicle can be predicted using an analytical model depending on launch site environment and weather conditions [541]. Predictions from a theoretical model of liquid rocket propellant vaporization rates for the source strength were compared to experimental results of the evaporation rate of UDMH in the natural environment [542].

The rate of evaporation from a UDMH leak that formed a liquid pool on the ground was measured as a function of variables, such as pool area, wind speed, temperature, and humidity [543]. An evaporation model was developed for predicting the downwind concentration of hazardous vapors in the event of a leak.

#### 1.6.3.4 Upper Stage Venting of Unused Propellants

The evaporation of NTO or UDMH in ambient air after residual propellants were dumped overboard from an upper stage is fast enough that droplets most likely will not reach the ground [544, 545]. The aerodynamic heating during the re-entry of upper stages is sufficient to vaporize and ignite residual UDMH in the propellant tanks. The concern about spills of unused propellants from re-entering second stages persists [546]. But most of the UDMH is scattered at impact areas from spent lower stages of launch vehicles in Kazakhstan.

To reduce the creation of space debris, and to minimize the chance of residual propellant impacting the surface, the residual propellants in upper stages have to be discharged after satellite-rocket separation. An analysis revealed that the propellant jets under the discharge conditions, once it has entered space, will break up into a large number of liquid droplets [547–549]. The droplets diffuse in a high vacuum, while gaseous molecules successively evaporate from the droplet surfaces. This process yields a rarefied vapor and droplet field around the final-stage rocket. The model was applied to three-dimensional rarefied vapor and droplet plumes arising from original and new, modified methods for in-orbit discharging of the residual UDMH fuel in a CZ-4B final-stage rocket. The calculation showed that the original venting method may lead to quite large disturbance moments beyond the rocket attitude-control recovery range, whereas the new venting method induced only very small disturbance moments.

The temperature changes of UDMH droplets, ejected into the upper atmosphere after the depressurization of upper stage fuel tanks, were modeled, taking into account the temperature gradient in the air after the depressurization of the fuel tanks at high altitude [550]. Falling droplets will assume spherical shapes. The temperature of the droplets is dependent on ambient temperature, pressure, droplet size, rate of evaporation, and heat transfer coefficient. The temperature of the small size droplets will be the same as the temperature of the atmosphere at altitudes of up to 40 kilometers.

#### 1.6.3.5 UDMH Contamination at Impact Sites of Spent Stages

Residual UDMH in the fuel tanks of Proton launch vehicles in Kazakhstan has caused widespread pollution when the spent stages impact the ground and may be responsible for health problems of people living near the designated impact areas [551].

Snow pollution from residual rocket propellants, UDMH and NTO, and their transformation products ([NDMA,  $(\text{CH}_3)_2\text{NNO}$ , nitrate  $\text{NO}_3^-$ , nitrite  $\text{NO}_2^-$ , and ammonium  $\text{NH}_4^+$ ]) within the impact regions of the first and second stages of Proton-M rockets launched from the Baikonur Cosmodrome were measured [552]. At the first stage in

the impact region in Central Kazakhstan, snow with a pH range from 1.7 to 9.0 was contaminated by *N*-containing substances in concentrations up to UDMH 0.27 g/L, NDMA 0.04 g/L,  $\text{NO}_3^-$  19 g/L,  $\text{NH}_4^+$  0.04 g/L, and  $\text{NO}_2^-$  0.13 g/L. The combined pollution in snow reached 81.6 g/m<sup>2</sup>. In the second stage, toxic substances released by rockets could not be detected in the impact region in the NE Altai, and the concentrations of  $\text{NO}_3^-$  and  $\text{NH}_4^+$  corresponded to the natural background levels.

The pre-impact plant communities in the Baikonur Cosmodrome area were inventoried to estimate their chance of survival under the conditions of spent rocket impacts [553]. The potential resistance of plant communities to the impact of rocket launch activities has been estimated, and the plants were categorized in three groups: weakly resistant phytocenoses, comparatively resistant phytocenoses, and contamination-resistant plant communities.

The post-impact natural return of vegetation to the crash site of a Proton-M launch vehicle near Baikonur Cosmodrome in the Republic of Kazakhstan was investigated [554]. The crash site area was sub divided into zones defined by differences in the character and intensity of disturbance. Since a launch failure in 2013, several field trips and geobotanical assessments were carried out in 2014 and 2017. Photos taken several years apart showed the gradual return of seasonal and perennial low tundra plants and bushes to the area. The contaminated topsoil of the immediate impact area had already been removed. Only the zone of total destruction of vegetation and zone of pyrogenic transformation still showed high levels of plant community modification.

#### 1.6.3.6 Decontamination of UDMH Spills

In one of the first thorough studies on UDMH (and hydrazine) spill decontamination, 94 different chemicals were reviewed for their suitability as spill control agents [555]. Eight solids were tested as decontaminants for 96%  $\text{N}_2\text{H}_4$  by dumping 5 g of solid onto 5 g of fuel. In the case of dry HTH, the mixture promptly ignited. There is considerably less information on the chemical decontamination of MMH or UDMH spills than on the treatment of hydrazine spills. Because UDMH boils at a lower temperature, unreacted UDMH is readily emitted from reacting solutions if the spill control agent ( $\text{NaOCl}$ ,  $\text{H}_2\text{O}_2$ ) concentration is too high. Five percent  $\text{NaOCl}$  or 30%  $\text{H}_2\text{O}_2$  will cause the mixture to boil in a few seconds. Lower concentrations, at 1%  $\text{NaOCl}$  or 5%  $\text{H}_2\text{O}_2$ , should thus be used for UDMH decontamination. Other chemicals tested as spill control agents included 1%  $\text{KMnO}_4$ , 5%  $\text{H}_3\text{BO}_3$ , 9%  $\text{NaHCO}_3$ , and carbonated water. These were effective in reducing the amount of UDMH escaping as vapor from the simulated spill to less than 0.2%. Only one of seven solid agents, a hydroxyethyl cellulose material, reduced the amount of UDMH escaping to 5% of that expected without solids treatment. Foam layers can also act as a blanket on UDMH spills.

One way to absorb and immobilize UDMH is by reaction with periodate-treated lignin sulfate (sulfate kraft lignin, black liquor, a waste stream from pulp and paper mills). Black liquor is a waste stream that otherwise has only a few other uses (vanillin, recovery of sulfur by burning it). Oxidation of sulfate kraft lignin with sodium perio-

date at a temperature of 328 K (55 °C) for 20 h results in a more than two-fold increase in the content of carbonyl and quinone groups and a three-fold increase in the sorption capacity for UDMH [556]. The sorbent can bind 6.7% of UDMH. In this respect, it is substantially better than other lignin-based sorbents. It was shown that the firm chemical binding of hydrazines to carbonyl groups in oxidized lignin hinders the desorption of UDMH, while the UDMH-saturated black liquor is disposed of by other methods. The same effect can be achieved by oxidizing lignin sulfate with hydrogen peroxide instead of sodium periodate [557]. An increase in the treatment duration from 15 to 120 minutes, and an increase in the concentration of hydrogen peroxide from 6 to 30%, did not have a significant effect on the functional composition and UDMH absorption properties of lignin.

If a propellant spill occurs, it would be useful to have a supply of a chemical agent for immediate application, e.g., a layer of foam or a gelling agent that reduces vapor emissions of the puddle of liquid temporarily until a more permanent solution to the problem can be found [558]. China continues to use UDMH as fuel in the early versions of Long March satellite launchers and has developed methods for the treatment of UDMH and NTO spills [559] (see also [560]).

When selecting oxidants for the neutralization of UDMH spills, one must ensure that the oxidizer selected will not result in the inadvertent formation of NDMA (“dimethylnitrosamine”), which is a potent carcinogen. An excess of HTH resulted in the formation of FDMH and tetramethyltetrazene, however, no NDMA was found [261]. An alternate method using a mixture of copper(II) sulfate (as a catalyst) and hydrogen peroxide produced substantial amounts of nitrosodimethylamine and is, therefore, not recommended. The destruction of UDMH was more complete if the hydrogen peroxide was added first, and was followed by the copper(II) sulfate.

#### 1.6.4 Decontamination of UDMH-Contaminated Equipment

It is common practice to calibrate flowmeters for liquid propellants in closed-loop flow benches before installing them on rockets and missiles. Flowmeters and other components wetted by UDMH or Ae-50 during such tests must be thoroughly decontaminated before installing them on vehicles. Decontaminating agents must be strong enough to destroy UDMH and hydrazine but should not cause corrosion of any of the components if they are intended to be re-used. The decontamination of equipment that is intended to be destroyed as part of a demilitarization effort could use more aggressive cleaning agents since the equipment will be dismantled and scrapped anyway.

A demilitarization, decontamination, and clean-up effort of one of the many sites in the former USSR that had to go through this process are described in [561]. This presentation provided an overview of the implementation of the Heptyl Infrastructure Elimination Project in Ukraine that was a part of the Cooperative Threat Reduction (CTR) program, which was jointly led by the US Department of Defense (DoD) and the Ukrainian Ministry of Defence (MoD). It described the equipment and services re-

quired to demilitarize rocket fuel storage sites (RFSS) by neutralizing and dismantling the infrastructure, including the neutralization and incineration of contaminated soil and Heptyl and Samin rocket propellant residuals from tanks and piping.

Tank cars that have been used for transportation or storage of UDMH or Ae-50 should be rinsed with water and then decontaminated. Several such cleaning methods have even been patented [562]. The tank should first be rinsed with a fluorochlorocarbon like Freon TF. The UDMH-loaded Freon should then be washed with water to remove the UDMH from the halocarbon, and the washed Freon can be distilled and re-used. Ultimately, the tank should be rinsed with an aqueous formaldehyde solution, followed by dilute hydrochloric acid, and then with water.

Another method proposed the decontamination of polluted shaped metallic surfaces via heat treatment using a high-temperature gas jet at 1573–1653 K (1300–1380 °C) with oxygen excess [563].

### **1.6.5 Disposal of UDMH**

The easiest way for disposing of surplus UDMH would be to feed it in a controlled manner into a flare stack with sufficient oxygen from the air to achieve complete combustion. In 1994 the US DoD signed agreements with the Ukraine and the Russian Federation under which the DoD was committed to providing both former Soviet Union states with equipment and other aid for use in eliminating their strategic missiles in accordance with schedules negotiated in the Strategic Arms Reduction Treaty. One specific need consisted of process equipment to treat or destroy pure ballistic missile liquid propellant components as well as vapor or purge gases, and to rinse fluids contaminated by UDMH, RFNA, or NTO. Incineration was considered as one possible treatment process. To supply data to demonstrate that incineration is a safe and effective treatment process, a series of tests with UDMH was conducted by the US EPA's Incineration Research Facility [564].

#### **1.6.5.1 Disposal of Concentrated UDMH**

Hydrazines that must be disposed of for some reason (e.g., contamination, surplus, demilitarization) can be destroyed by burning, autoxidation, or chemical oxidation.

#### **1.6.5.2 Demilitarization of Surplus UDMH**

At the end of the Soviet era, due to missile build-up, large amounts of UMDH (“Heptyl”) and dinitrogen tetroxide (“Amyl”) and high-density RFNA (“Melanj”) had to be disposed of in a safe and environmentally acceptable manner. This was part of the Strategic Arms Reduction Talks (START) and Strategic Arms Limitation Talks (SALT) and the CTR program, [565]. The Nunn-Lugar program was assisting in the reduction of the SS-18 missile threat to the US and with the demilitarization of the propellants. This involved a chain of custody, destruction, dismantlement, and demilitarization of strategic weapons. Between 1992 and 2010, 8790 M\$ were authorized for these tasks.

Most of this went towards transportation, storage security, and the disarmament of nuclear warheads. Only a smaller portion went towards the destruction of delivery missiles (launchers) and their propellants. The US provided a substantial amount of funding to build demilitarization plants where the propellants were to be converted to other potentially useful, inert chemicals that were no longer to be used as rocket propellants. The facility to be built in Sergei Posad, some 70 km from Moscow, was to be constructed with US aid under the Nunn-Lugar technical assistance program. It appears that it intended to use a process other than burning since there were plans to use conversion products (perhaps amines?) in the manufacture of dyes. In addition to financing the plant construction, the US also supplied a fleet of railroad tank cars that were to be used for the interim storage and transportation of the chemicals to the centralized destruction plant. One project funded in this category, the construction of a plant to dispose of liquid fuel removed from Soviet ICBMs, raised concerns among some members of US Congress during the Bush Administration. The US constructed the facility at a cost of nearly \$100 million. However, before construction was completed, Russia had already used much of the fuel instead in rockets in its commercial and military space-launch program. Consequently, in 2002, Russia informed the US that it did not have any fuel for the facility. Representative Duncan Hunter stated that the episode represented an example of the potential for waste in the Cooperative Threat Reduction (CTR) program. Others, however, noted that, although unfortunate, this case was the exception in a program that has spent more than \$4 billion on threat reduction projects. As it turned out, much of that equipment was never used because the post-USSR powers-to-be sold much of the military propellants to China and/or diverted the propellants to commercial space launch vehicles.

It would be interesting to review statistical data about how much UDMH has actually been destroyed under that program and which techniques were used. A brief Internet search revealed numerous pieces of information but they could not be independently verified and the following survey may not be complete. Numerous international conferences have been devoted to the subject of cleaning up contaminated former military sites so that the areas can be returned to civilian use [566]. Most of the concern at these conferences was about spilled halogenated solvents, transformer oils, and hydrocarbon fuels that have permeated into the ground and aquifers. Some reports list UDMH alongside problems with the disposal of plutonium and chemical warfare agents. The problem with the disposal of UDMH is dwarfed by the problems associated with the disposal and accountability of these other chemicals. Only a few reports are specific for hydrazine-type missile fuels. Some discuss UDMH disposal in connection with the disposal of other liquid rocket propellants, such as Samin (a mixture of xylidine and triethylamine that is similar to the TONKA fuels used by the Germans in surface-to-air missiles toward the end of World War II) or dinitrogen tetroxide (code name: Amyl).

At least 52 heavy ICBMs of the SS-18 type were disposed of in Kazakhstan after more than 30 years in service. They were transported to the Nizhny Novgorod region

in 1995–1996 and destroyed. Approximately 6000 tons of off-loaded UDMH were available in Kazakhstan; it was transported to Russia. Approximately 130 ballistic missiles of the SS-19 type were transported from Ukraine to Russia in 1995–1996 and destroyed. The fate of the off-loaded UDMH (about 4000 metric tons) remains unknown.

The US DoD agreed in 1996 to assist Kazakhstan in the neutralization and dismantlement of missile unified fill facilities (UFFs) for SS-18s located at Derzhavinsk, Zhangis-Tobe, and Leninsk, and to provide assistance with the elimination of liquid fuel, possibly using an incinerator. Each UFF complex consisted generally of above-ground liquid ICBM fuel (heptyl) and oxidizer (amyl) storage tanks, mechanical equipment located inside buildings, earth-covered semi-buried bunkers and structures, buried distribution piping and utilities, lagoons, and communication systems. In addition to surface-launched ballistic missiles, propellant from the Northern and Pacific fleets, using two-stage, liquid propellant, submarine-launched, ballistic missiles RSM-25, RSM-40, RSM-50, and RSM-54, needed to be demilitarized. Submarines equipped with these missiles were based in three bases of the Northern fleet (Yagelnaya, Olenya, and Ostrovnoy) and two bases of the Pacific Fleet (Rybachiy and Pavlovskoye). A news item released in July 2000 quotes a Russian official stating that 2750 tons of liquid rocket propellants (that number most likely includes both oxidizer and fuel) were still stored in the province of Primorye near Vladivostock and that there was concern about corrosion and leaking of storage tanks. Thousands of SA-2 surface-to-air defense missile systems using UDMH may still be scattered in remote bases, and some are not even accounted for. The SA-2 and the SCUD tactical missile use the same propellants. This situation was substantially worse than the situation in the US during the 1970s when several hundred Nike missile sites were decommissioned, leaving cleaning solvent and propellant contamination behind.

One of the several UDMH disposal facilities was planned to be built near the Russian town of Sergiev Posad, which caused some concern in the community with regards to the safety of the installation. Estimates of how much heptyl was stored in Russia's former "closed cities," the Soviet-era secret towns like Sergiev Posad (known as Zagorsk in Soviet days), ranged from 50000 to 150000 tons. At the Scientific Research Institute of Chemical and Construction Machines (SRICCM) based in Sergei Posad, there were over 100 tons of heptyl in storage. After the new reprocessing facility was installed, at least another 10000 tons were planned to be brought there from other sites in Russia. After diluting the UDMH with copious amounts of water, the methods described in this chapter for UDMH wastewater decontamination can be used for the controlled disposal of UDMH with a minimum of toxic waste products.

In the US, demilitarization of decommissioned LANCE Intermediate Range Ballistic Missiles (IRBMs) posed a smaller problem in terms of disposing of IRFNA and UDMH propellants that had been off-loaded from missiles [567]. Some of the decommissioned LANCE missiles were later used as practice targets for anti-ballistic missile interceptor field tests.

### Disposal of UDMH by Burning and Incineration

The two-stage combustion of hypergolic rocket propellants ( $\text{N}_2\text{O}_4$  and the three hydrazine fuels) in an optimized burner was expected to lead to a minimum discharge of  $\text{NO}_x$  into the environment [568]. The first stage of combustion allowed the fuel or oxidizer to react in a respectively lean or rich flame, yielding a mixture of products including the inevitable  $\text{NO}_x$ . The second stage of combustion was supposed to achieve the reduction of  $\text{NO}_x$  as the result of the addition of  $\text{NH}_3$  or  $\text{H}_2$  (thermal  $\text{DeNO}_x$ ) or cyanuric acid. The objective was to understand and control the turbulent combustion of these propellants through the application of fluid dynamics and kinetics modeling in conjunction with optical and mass spectrometer-based flame diagnostics.

There are several incinerator-burner designs that were qualified and certified for the destruction of chemical warfare agents; these should work for the less toxic and more reactive hydrazines. A toxic waste burner has been built and evaluated for the burning of UDMH with a hot gas (pre-burner) and additional air [569]. The goal was to reduce  $\text{NO}_x$  emission in the exhaust gases down to less than 165 ppm. Initially, hydrazine and UDMH were tested in an existing air-cooled liquid incinerator with natural gas being used for ignition (in some cases, it was necessary to sustain combustion). Air was used as the oxidizer. UDMH could be destroyed by incineration down to a level below 2 ppm residual hydrazines with  $\text{NO}_x$  emissions in the discharged gas in concentrations well below 165 ppm. Incinerator dwell times were in the order of 0.1 s.

Another burner developed for the removal of liquid propellants disposed of over 453 kg/h (1000 lb<sub>m</sub>/h) of liquid propellants, including hydrazine, by burning it in the air to produce exhaust gases in the 977 K (1300 °F) range. The exhaust gases contained acceptably low levels of nitrogen oxides [570].

The US Environmental Protection Agency (EPA) Risk Reduction Engineering Laboratory conducted NTO and UDMH destruction tests in a rotary kiln incinerator with afterburner and wet scrubber [564, 571]. In the test program, the two propellant components were independently incinerated in separate sets of triplicate tests. The six UDMH destruction tests were performed at a nominal kiln exit gas temperature of 1153 K (980 °C = 1800 °F). UDMH was sprayed into the combustion chamber without any auxiliary hydrocarbon fuel. All tests were performed at a primary combustion chamber exit gas temperature of nominally 1153 K (980 °C = 1800 °F) and a secondary combustion chamber (afterburner) exit gas temperature of nominally 1363 K (1090 °C = 2000 °F). 1363 K (1090 °C = 2000 °F). The flue gas from the afterburner was passed through a wet scrubber. The test program results showed that  $\text{NO}_x$  levels were in the range of 690 to 780 ppm at 7%  $\text{O}_2$  at the primary combustion chamber exit during UDMH incineration. These were reduced to 410 to 500 ppm at 7%  $\text{O}_2$  at the secondary combustion chamber exit, largely due to the dilution that accompanies the addition of the extra fuel and air required to raise the secondary chamber's temperature. The scrubber exit levels were similar to those at the secondary chamber exit, at 440 to 500 ppm at 7%  $\text{O}_2$ . No unreacted UDMH or NDMA was detected at any flue gas location.

### Catalytic Combustion

Investigators at the Russian Boreskov Institute of Catalysis proposed the destruction of UDMH in a fluidized bed catalytic combustor. A similar process had been developed for the disposal of mixed organic radioactive waste. During the low-temperature stage of the catalytic combustion process (873–1023 K), the  $\text{NO}_x$  formation is minimal. The air-to-fuel ratio will be carefully selected to minimize  $\text{NO}_x$  formation. A pilot plant with a capacity of 2 kg/h was developed. The ultimate design envisioned a plant capable of destroying 100 tons of UDMH/yr.

### UDMH Disposal by Hydrogenolysis and Reduction

To obtain products of commercial value from the disposal of UDMH, the hydrogenolysis over a supported platinum group catalyst in the presence of excess hydrogen leading to ammonia and DMA has been patented [333–336].

UDMH in aqueous solutions can be disposed of by passing the heated mixture with excess hydrogen gas through a catalytic reactor, thus forming DMA and ammonia [572, 573]. The ammonia can be dissociated, and the hydrogen thus formed is fed back into the first reactor. The apparatus can be built on skids so that it can be transported to remote sites where surplus UDMH needs to be destroyed.

Raney-nickel Al/Ni alloy in caustic 0.5-M NaOH was tested for the destruction of UDMH, NDMA, MMH, and hydrazine [574]. The following pathway for the reductive decomposition of NDMA creates UDMH as an intermediate, which ultimately is reduced to DMA and ammonia:

Besides Raney nickel, Al powder in 0.5-M NaOH, stannous chloride in methanol, and granular tin metal in concentrated hydrochloric acid were tested for the destruction of DMAZ.

### Conversion of Surplus UDMH to Other Chemicals with Commercial Value

It has been repeatedly attempted to convert UDMH and RFNA into commercially useful products. However, this is a difficult task. Even if it is technically feasible, the question remains of whether it can be done profitably [575]. Considering the problem of recycling unwanted UDMH, eight saturated aliphatic aminimides with low melting points were synthesized and the structures, melting points, and pyrolysis were determined by FTIR [324]. Some of the amines can be used in the synthesis of surfactants [331]. It has also been proposed to convert UDMH to its oxalate salt, which is relatively insoluble and stable for storage in air. UDMH oxalate can possibly be used in the PUREX process for nuclear fuel element reprocessing and radioactive isotope separation [505].

### Plasma Pyrolysis

No  $\text{NO}_x$  at all was formed when UDMH was destroyed in a steam reforming plasma burner. The plasma energy recycle and conversion (PERC<sup>TM</sup>) process for the demilitarization of propellants and explosives uses an induction-coupled plasma (ICP) torch as a heat source in a reaction chamber system to convert wastes into by-products in a safe and environmentally clean manner [576–578]. In the PERC<sup>TM</sup> process, combustion of a supplementary fuel is not necessary. The conversion process can be carried out in any reaction environment, such as an oxygen-free, reducing, steam reforming, or oxygen-rich environment. This ability to choose and control the reaction environment permits the control of the by-products formed by the process. For example, conventional destruction of UDMH in an incinerator can result in the production of  $\text{NO}_x$  as a reaction product. The PERC<sup>TM</sup> system, using the steam reforming process, will convert UDMH into carbon monoxide and hydrogen along with nitrogen gas. Destruction efficiency demonstrated in all cases was greater than 99.999%, and for certain materials, it was greater than 99.99999%. The first PERC<sup>TM</sup> system capable of processing up to 113 kg/h (250 lb/h) of liquid organic waste materials was installed in 1995.

### Hazards of Inadvertent Nitrosamine Formation During the Disposal of Alkylhydrazines

Four different methods were evaluated for the decontamination and destruction of hydrazine-based carcinogens, including a hydrazine-based pharmaceutical, in laboratory wastes: reduction with nickel/aluminum alloy in alkaline solution, oxidation with potassium permanganate in sulfuric acid solution, potassium iodate, and hypochlorite solutions [579, 580]. The reliable and environmentally-safe destruction of laboratory wastes by these four methods was verified by checking their mutagenicity before and after treatment with one of the four methods. Nitrosamines were detected when UDMH or MMH was oxidized with hypochlorites. The reductive destruction of hydrazines and nitrosamines by reaction with Raney nickel in alkaline solution was recommended several times, however, the problem with disposing of large volumes of aluminum hydroxide sludge with nickel (itself a suspect carcinogen) was not addressed [581, 582]. The incomplete reduction of NDMA would form UDMH as an unwanted intermediate, making this an undesirable option also. One group tested the reduction of ten different nitrosamines, including NDMA, with aluminum metal strips in caustic solutions. However, they failed to analyze the resulting solutions for hydrazines [583]. Nitrosamines are not truly destroyed if the waste still contains hydrazines that will readily oxidize back to nitrosamines as soon as air is admitted. We are limiting our discussion here only to the disposal of hydrazines and cannot provide a complete summary of the various methods for the destruction of nitrosamines. There are other publications that deal specifically with nitrosamines and contain chapters on nitrosamine disposal [584, 585]. Other nitrosamine environmental and toxicity discussions are detailed later in this chapter.

### 1.6.6 UDMH Wastewater Decontamination

Many different methods were tested for the decontamination of UDMH-containing wastewater, which is a more difficult task than the decontamination of either hydrazine- or MMH-contaminated waters. Although UDMH is no longer in use in the United States, the techniques described here are equally effective for decontamination of wastewater containing MMH. Several decontamination techniques were used to clean up stored process waste and tank rinse water [586]. The treatment technologies and methods UDMH wastewater decontamination included physical, biological, and chemical methods. Methods evaluated for UDMH decontamination included ozone oxidation, natural degradation, ion exchange resin, active carbon adsorption,  $\text{TiO}_2$  photo-catalytic oxidation, and biological remediation [587–589]. Many wastewater treatment techniques used for the removal of other contaminants can also be used for the treatment of MMH- or UDMH-contaminated wastewater [590].

UDMH that is being oxidized on purpose as a means of disposal and decontamination of UDMH-polluted rinse waters will rarely turn directly into carbon dioxide, nitrogen, and water, which are the desired oxidation products. Intermediate species have been analyzed by gas chromatography-mass spectrometry. The effectiveness of various chemical oxidants in respect to the main intermediates of UDMH oxidation, such as 1-formyl-2,2-dimethylhydrazine, dimethylaminoacetonitrile, NDMA, and MTA, was measured using Fenton's reagent, potassium permanganate and sodium nitrite [591]. Quantitative analysis was performed using HPLC. Oxidation products were identified by GC/MS in combination with SPME. 1-Formyl-2,2-dimethylhydrazine was completely oxidized by Fenton's reagent with the formation of formaldehyde *N*-formyl-*N*-methyl-hydrazone. 1,4-dihydro-1,4-dimethyl-5*H*-tetrazol-5-one was oxidized by the action of potassium permanganate. *N*-Methyl-*N*-nitro-methanamine was formed in the presence of sodium nitrite. Oxidation of 1-formyl-2,2-dimethylhydrazine also resulted in the formation of NDMA. Oxidation of dimethylaminoacetonitrile proceeded with the formation of hydroxyacetonitrile, DMF, and 1,2,5-trimethylpyrrole. After 30 d, dimethylaminoacetonitrile was not detected in the presence of Fenton's reagent and potassium permanganate but its concentration in samples with sodium nitrite remained 77 mg/L. In the presence of Fenton's reagent, potassium permanganate, and sodium nitrite after 30 d, NDMA concentration decreased by 85, 80, and 50%, respectively. In a control sample without nitrite, NDMA concentration decreased by 50%, indicating that sodium nitrite had no effect on NDMA decay. Only Fenton's reagent achieved the reduction of the concentration of MTA to 50% in <30 d. In the presence of other oxidants, MTA concentration decreased only by 15–20%. As a result of these experiments, Fenton's reagent turned out to be the most effective oxidant for the destruction of UDMH.

Throughout those dark ages of hydrazine chemistry when UDMH was still made by the reduction of NDMA, the removal of waste NDMA from process streams was a difficult problem. The waste stream generated in the production of UDMH contained approximately 200 mg/L of NDMA, 25% sodium hydroxide, and 5% nitrite. Various

techniques for the removal of NDMA from wastewater were tested including wet air oxidation [592]. From the limited data evaluated, it was suggested that NDMA was amenable to destruction by wet air oxidation to approximately the 1 mg/L level with relative ease. Reduction below the 1 mg/L level, however, was very difficult. The fact that some NDMA was carried out with the sparging air instead of being oxidized in solution was carelessly neglected by early investigators. The limit of NDMA detection at that time was approximately 20 µg/L. More sensitive analytical methods have become available in the interim. UDMH is now made by a different route that does not involve NDMA as an intermediate.

The US EPA at one point declared wastes generated during the manufacturing of UDMH and daminozide as hazardous wastes under the Resource Conservation and Recovery Act (RCRA) [593, 594].

The wastewater from UDMH production in the Qinghai province in China contained high concentrations of organics, ammonia, chloride ion, salinity, and highly toxic substances. A combined process of ammonia-stripping and advanced oxidation technology/activated carbon adsorption was designed to treat the sewage [595]. The capacity of this installation was 25 m<sup>3</sup>/h. An examination showed that the treatment system was stable and efficient and met wastewater discharge standards.

It is common practice to characterize various competing UDMH decontamination processes by the efficiency of the COD removal. While it is good that the COD is decreased by more than 98%, these investigations often ignored the formation of toxic by-products that do not have a COD.

Until recently, the assessment of the effectiveness of oxidative reagents for the cleanup of wastewaters and soils polluted with UDMH was mostly based on the residual content of UDMH and did not take into account the possibility of the formation of a large number of potentially dangerous, equally toxic nitrogen-containing transformation products [596]. High-resolution Orbitrap MS was used to characterize UDMH transformation products formed by the action of atmospheric oxygen and different pollution control oxidants (Fenton's reagent, KMnO<sub>4</sub>, HOCl, H<sub>2</sub>O<sub>2</sub> in the presence of Cu<sup>2+</sup> and [Fe(EDTA)] catalysts) which are typically used to detoxify spill sites. The analysis of transformation products revealed 303 compounds of various chemical structure classes. Several major products were detected that were not previously described in the literature. It was established that none of the investigated oxidative reagents ensure the complete conversion of UDMH to safe compounds. The hydrogen peroxide-based reagents, particularly the H<sub>2</sub>O<sub>2</sub> + Na[Fe(EDTA)] system often used in Kazakhstan, form the greatest number of transformation products, for many of which toxicity information was not available. The majority of the compounds found in model solutions were detected in extracts of soil from the crash site of a Proton launch vehicle that had been subjected to on-site decontamination. With each successive treatment, the number of detectable UDMH transformation products decreased. The most enduring compounds were the amines.

#### 1.6.6.1 UDMH Wastewater Decontamination by Ozone Treatment

Neither MMH nor UDMH in aqueous solution become completely oxidized to  $N_2$  and  $CO_2$  by ozonization in the dark but they can be effectively destroyed by combined UV ozonolysis [285, 286]. Mechanisms of various photolytic reactions of alkylhydrazines and nitrosamines were summarized earlier in this chapter (in Section 1.4.6.) The ozone/UV treatment can also be used for the decontamination of other hazardous waste streams [597]. One way to assure reliable, environmentally safe, and complete destruction of toxins in wastewaters by ozone is to check their mutagenicity before and after ozonation treatment [598]. Other space-faring nations like China have now also resorted to the use of UV-ozonolysis as a means of UDMH removal from wastewater [599].

The rates of oxidative destruction of hydrazine, MMH, or UDMH were investigated using ozone alone or ozone with UV [600]. All three hydrazines were oxidized rapidly with ozone or ozone/UV. The ozone was consumed as rapidly as it was introduced for as long as any hydrazine was present. The limited solubility of ozone in water is one of the rate-limiting factors. NDMA was formed as an intermediate from the methylhydrazines, but it was destroyed by continued and extended ozone treatment. Its destruction rate was significantly slower than that of the hydrazines. Contrary to the findings of other investigators, the use of UV did not appreciably enhance the destruction rate of NDMA except at high concentrations. No apparent acceleration of the ozone/UV destruction rate of NDMA was observed as the result of placing stainless steel CRES-304 panels or nichrome wire mesh into the reactor as surface catalysts. However, tungsten, both in the shape of USS No. 100 (100 mesh) powder and metal plates, accelerated the destruction of NDMA and changed the type of unwanted by-products formed. Metal catalysts accelerated the destruction of hydrazines and NDMA [601]. The tungsten plate did not lose activity after ten consecutive tests. Tungsten powder accelerated the rapid destruction of NDMA to levels below 30 ppt (detection limit). The addition of 1.2 ppm of  $Cu^{2+}$  or 15 ppm of  $Fe^{3+}$  ion to the solution surprisingly delayed the apparent NDMA destruction at concentrations below 0.1 ppm. This effect was hard to explain. It was assumed that some NDMA was complexed and protected in metal complexes and was only gradually released for photolysis. In addition to testing the metal ions by themselves, the two ions should have been tested in combination for synergistic, thus potentially accelerating effects. Starting with a mixture of 1% of each of the two methylhydrazines and in the absence of catalysts and at pH 9.5, the NDMA concentration peaked at 2000 ppm shortly after all hydrazines were consumed. NDMA destruction was reasonably fast down to a concentration of 1 ppm but became very slow at lower concentrations. If the same test was performed at pH 2.5, net NDMA production was less than observed at higher pH, and NDMA destruction rate reduced quickly down to concentrations as low as 0.01 ppm. This observed pH dependence was in contrast with results reported by other investigators [285, 286], where operation at pH 9.1 for the destruction of hydrazines was recommended (but apparently the rate of NDMA destruction was ignored). With no pH control, and starting

with typical wastewaters at pH 10, the pH dropped with progressive waste neutralization by ozone-UV. This would indicate that no pH adjustment prior to or during the process is required. The addition of acid or caustic during a test run increases the volume of the waste solution. Such additions would be done only for development tests to determine the effect of pH variation but are not needed for the actual operation of a commercial unit. The rate at which the three hydrazine fuels were destroyed was about six times slower at pH 2.5 than at 9.5. However, the concentration of NDMA at the time that the hydrazines were gone was an order of magnitude less than that during the treatment at high pH [602]. Three different methods for the treatment of hydrazine(s) wastewaters were tested at the IITRI: ozone as the primary oxidizing agent, UV light as a catalyst for the reaction between NDMA and ozone, and finally, chlorine as a final “polishing” agent following the treatment with either of the two aforementioned methods [603]. Three different reactors were used in the study: a tubular reactor containing a liquid column and a gas dispersion (sparging) element at the bottom, a UV spray chamber with two different quartz lamps (high-pressure and low-pressure mercury lamps), and a commercial UV water purifier consisting of a CRES-316 tube with a coaxial quartz tube holding the UV lamp. It was shown that chlorination, even as a “polishing” treatment, produces chlorinated hydrocarbons. Chlorination was not pursued any further because halocarbons are not permitted in the effluent of the treatment plant. The combination of ozone and UV was able to reduce the NDMA concentrations to below 20 ppt.

Tests with an ozone/UV pilot system at a flow rate of 3.78 L/min (1 gpm) and ozone pre-saturated water showed that initially the NDMA concentration was increased due to incomplete oxidation of UDMH in the raw feed water [604]. Improved destruction of NDMA was possible by injecting the ozone at the UV lamp, which emitted light at 253.7 nm. The first full-scale system was a batch operation with water recirculation, treating 3000 gal in 18 h. However, it was still too slow to keep up with demand. The reaction time of an improved system with additional UV lamps was at least eight to 10 h to achieve a residual NDMA concentration of less than 1 ppb in accordance with then-applicable regulations.

The ozonization of UDMH can be accelerated by conducting it in a suspension with catalysts [605]. The wastewater treatment by oxidation of UDMH with ozone (without UV) can be improved by iridium catalysts. The catalysts consisted of 30%, 10%, or 3% iridium on alumina. This would be a very expensive approach and may not be economically justifiable, considering the cost of iridium catalysts. It may not provide complete removal of NDMA either.

Ozonation (also referred to as ozonization and ozonolysis), in combination with UV illumination, has been used in drinking water sterilization with good success. Commercial ozonization units are available from several vendors to destroy dissolved organic contaminants present in ground water and wastewater with low levels of suspended solids [606]. The system uses a combination of UV radiation, ozone, and hydrogen peroxide to effectively oxidize most contaminants.

An ozone/UV treatment was used for the decontamination of hydrazine(s) wastewater at Rocky Mountain Arsenal [607]. The main concern was about residual NDMA left behind long after all UDMH was all gone.

NASA's White Sands Test Facility (WSTF) fabricated and tested a full-scale 85.2 m<sup>3</sup> (2250 gal) UV/ozonation hydrazine wastewater treatment system [608]. A series of 21 tests evaluated the performance of the system using synthetic mixtures of hydrazine, MMH, and UDMH at 100 and 3900 ppm concentration levels. In addition, one of these tests was performed on actual wastewater obtained from a Vandenberg Air Force Base launch site sump. The tests demonstrated that the UV ozonation system would satisfactorily reduce the hydrazine concentration to less than 5 ppb and the NDMA concentration to less than 100 ppt. The same UV-ozonolysis installation that was originally developed for hydrazine waste can also be used for the destruction of other industrial organic wastes generated during routine operations [609, 610].

A combination ozone/UV decontamination unit designed by IITRI was tested at NASA's WSTF. Once again, actual wastewaters collected from rocket test sites at WSTF and USAF VAFB were used. In 1988, the USAF Space Systems Division requested that NASA's WSTF fabricate and conduct performance evaluation tests on a full-scale prototype 8.52 m<sup>3</sup> (2250 gal) hydrazine wastewater treatment system [611]. The system consisted of three skid-mounted units, thus providing portability. The system was designed to reduce hydrazine fuel concentrations to non-detectable quantities (less than 5 ppb) and reduce NDMA to less than 100 ppt. The system uses ozone and UV light to destroy the hydrazine fuels and their by-products. Ozone concentrations of up to 5.7 mass-% O<sub>3</sub> in O<sub>2</sub> were possible. The UV lamp provided 3 kW of UV energy with 85% at the resonance line of 254 nm. To evaluate system performance under various operating conditions, tests were performed with fuel concentrations from approximately 100 to 6000 ppm, and while using various techniques for introducing the ozone into the wastewater. The system was able to reduce fuel concentrations to less than the 5 ppb detection limit and NDMA to less than 100 ppt. The system was also able to reduce the fuels in actual VAFB launch pad water that contained 300 to 400 ppm fuels to less than 5 ppb fuel and 100 ppt NDMA. The system operated as designed with one exception: the spargers used for introducing the ozone/oxygen gas stream into the water had to be altered. Examination of the gases exiting the reactor tanks vent indicated that the ozone destruct unit performed well, with no traces of ozone being emitted. Analytical testing of these exhaust gases did show low concentrations of several organic compounds. Readings taken sporadically throughout this test series with a fuel Interscan<sup>®</sup> detector indicated no traces of propellant fuel. Tungsten plates as stationary catalysts were used to catalyze the NDMA destruction.

A study of the effects of Ni/Fe catalysts on UDMH decontamination in wastewater using ozonation found that the catalysts exhibited high activities for the ozonation of UDMH [612]. The catalysts content, pH, and the initial UDMH concentration had little effect on the performance of the catalysts. The catalysts were characterized by

XRD, and the results showed that they had the spinel-type structure of magnetite and FeNi<sub>3</sub> alloy.

NDMA and UDMH can be destroyed by oxidative degradation of NDMA using conventional ozonization and an advanced oxidation process using ozone/hydrogen peroxide. The rate constants of reactions of NDMA with ozone and hydroxyl radical ( $\cdot\text{OH}$ ) were determined to be  $0.052 \pm 0.0016 \text{ mol}^{-1} \text{ s}^{-1}$  and  $(4.5 \pm 0.21) \times 10^8 \text{ mol}^{-1} \text{ s}^{-1}$ , respectively [613]. The reaction with  $\cdot\text{OH}$  dominates the NDMA oxidation during ozonization. Conventional ozonization with up to  $160 \mu\text{M}$  ( $7.7 \text{ mg/L}$ ) ozone led to less than 25% NDMA oxidation in natural waters.

UDMH wastewater was treated with ozone  $\text{O}_3$ ,  $\text{O}_3/\text{UV}$ , and  $\text{O}_3/\text{VUV}$ . The most efficient process was  $\text{O}_3/\text{VUV}$ . Its rate constant was 39.8 and 65.6% higher than  $\text{O}_3/\text{UV}$  and  $\text{O}_3$  without UV, respectively [614]. The degradation intermediate formaldehyde could also be removed very quickly in the  $\text{O}_3/\text{VUV}$  process and its concentration was lowered to be undetectable within 50 minutes. The dependence of reaction efficiency on several operating parameters such as initial pH, ozone feed rate, and carbonate addition was also studied. The experimental results showed that the UDMH degraded fastest when the initial pH was nine and the corresponding rate constant reached  $0.4461 \text{ min}^{-1}$ . The rate constant increased linearly with the ozone feed rate. The apparent degradation kinetics of UDMH changed from first-order to zero-order kinetics when the initial concentration of UDMH increased from 100 to 2000 mg/L. Carbonate addition in the range of 0–2 mmol/L had little effect on UDMH degradation. The formation of inorganic nitrogen ionic compounds including  $\text{NO}_2^-$ ,  $\text{NO}_3^-$ , and  $\text{NH}_4^+$  during reaction was identified. It was found that inorganic nitrogen that existed mostly in the form of  $\text{NH}_4^+$  only accounted for 40–60% of the total nitrogen, which implied that other nitrogen-containing organic intermediates were formed during UDMH degradation.

The NDMA formation from ozonation of six hydrazine compounds was investigated. It was found that NDMA formation yields from treatment of UDMH-contaminated groundwater (pH 7) were 7.5–89% [615]. Results in the presence of *tert*-butyl alcohol as a radical scavenger indicated that NDMA was formed by reaction with molecular ozone except for tetramethyltetrazene. From the results of effects of pH, *tert*-butyl alcohol, and water matrix (groundwater and river water), it was suggested that reactions of tetramethyltetrazene with ozone and/or hydroxyl radicals were responsible for NDMA formation. Because NDMA formation on chloramination was low, there are other NDMA precursors present during ozonation in actual water treatment.

It is surprising to find that NDMA may form during wastewater treatment with ozone, even in the absence of UDMH. There are other organic contaminants in wastewater that will be converted to NDMA. UDMH was among the several organic compounds shown to end up as NDMA as the result of ozonization [616]. Nitrosamine formation may be a significant barrier to ozonization in water re-use applications (even away from any rocket test sites), particularly for direct or indirect potable re-use since studies showed direct NDMA formation during ozonization of natural

water and treated wastewaters. Several precursor compound solutions, prepared in ultra-pure water and treated wastewater, were subjected to a 10M excess of ozone. The study discovered six new NDMA precursor compounds that had not been previously reported in the literature. The presence of bromide was important for three compounds (1,1-dimethylhydrazine, acetone dimethylhydrazone, and dimethylsulfamide) but did not enhance NDMA formation for the other precursors.

UDMH forms NDMA during ozonation but the relevant reaction chemistry was not quite understood. An investigation of the reaction kinetics and mechanisms of NDMA formation during the ozonation of UDMH and daminozide (DMZ, SADH) showed that the reaction of ozone with these NDMA precursor compounds was fast, and  $k_{O_3}$  at pH 7 was  $2 \times 10^6 \text{ mol}^{-1} \text{ s}^{-1}$  for UDMH [617]. Molar NDMA yields (i.e.,  $\Delta[\text{NDMA}]/\Delta[\text{precursor}] \times 100$ ) were 84% for UDMH, as determined at the molar ozone dose ratio ( $[\text{O}_3]_0/[\text{precursor}]_0$ ) of  $\geq 4$  in the presence of *tert*-butanol as a hydroxyl free radical (OH) scavenger. The molar NDMA yields decreased significantly in the absence of *tert*-butanol, indicating  $\cdot\text{OH}$  formation. Its subsequent reaction with the parent precursors formed negligible NDMA. The  $k_{OH}$  at pH 7 was  $4.9 \times 10^9 \text{ mol}^{-1} \text{ s}^{-1}$  for UDMH. Reaction mechanisms were proposed in which an ozone adduct was formed at the nitrogen next to *N,N*-dimethylamine that decomposed via homolytic and heterolytic cleavages of the  $-\text{N}^+-\text{O}-\text{O}-\text{O}^-$  bond, forming NDMA as a final product. The heterolytic cleavage pathway explains the significant OH formation via radical intermediates. Overall, significant NDMA formation was found to be unavoidable during ozonation or even during the  $\text{O}_3/\text{H}_2\text{O}_2$  treatment of waters containing UDMH due to their rapid reaction with ozone-forming NDMA with a high yield.

The majority of UDMH wastewater treatments produce lots of toxic by-products; among these, NDMA causes the most concern because it is a strong carcinogen. The compositions of the by-products are important for evaluating the treatment efficiency and understanding the UDMH degradation mechanism to achieve complete UDMH mineralization (i.e., conversion to  $\text{CO}_2$ ,  $\text{N}_2$ , and water). The intermediate and end products of UDMH treatment with different oxidants were investigated by using a simple and fast method, which was SPME in combination with GC-MS [618]. The effects of several parameters (coating fiber, salt addition, pH, sampling time, and desorption time) were studied to optimize analyte recovery. The best response can be attained by the  $65 \mu\text{m}$  PDMS/DVB fiber at pH 7 over ten minutes after desorption over one minute in the GC inlet. The intermediate and final oxidative products of UDMH wastewater treatment with different oxidants ( $\text{O}_3$ ,  $\text{Mn}^{2+}/\text{O}_3$ , or  $\text{Fe}^{2+}/\text{H}_2\text{O}_2$ ) were investigated. The results showed that the UDMH treatment with  $\text{O}_3$  could lead to unwanted high yields of NDMA. Metal catalytic ozonation could largely minimize the formation of NDMA. No NDMA was observed in the final decontaminated samples after treatment with Fenton's reagent,  $\text{Fe}^{2+}/\text{H}_2\text{O}_2$ .

### 1.6.6.2 UDMH Wastewater Decontamination via Hydrogen Peroxide Treatment

The decontamination of wastewater containing UDMH can be achieved by catalytic oxidation, using air or  $\text{H}_2\text{O}_2$  as the oxidant [619]. With the addition of activated carbon as an adsorbent or by lengthening the time of purification, the discharge concentration of UDMH in the wastewater could be reduced to 0.5–0.8 mg/L, and that of the secondary pollutant formaldehyde could be reduced to 1.3–2.0 mg/L.

Degradation reactions of UDMH using atmospheric oxygen and hydrogen peroxide were carried out in the presence and absence of copper ion catalysis and at varying pH [251]. Reactions were also carried out in the presence of hydrazine, which is a constituent, along with UDMH, of the rocket fuel Aerozine-50. In the presence of copper, UDMH was degraded by air passed through the solution. The efficiency of degradation increased as the pH increased but the carcinogen NDMA was formed at neutral and alkaline pH. Oxidation was not seen in the absence of copper. NDMA formation occurred even at copper concentrations of <1 ppm. Oxidation of UDMH with hydrogen peroxide also gave rise to NDMA. When copper was absent, degradation of UDMH did not occur at acid pH but when copper was present with hydrogen peroxide some degradation occurred at all pH levels investigated. The production of NDMA occurred mostly at neutral and alkaline pH. In general, higher concentrations of hydrogen peroxide and copper favored the production of NDMA. DMA, methanol, FDMH, formaldehyde hydrazone, and tetramethyltetrazene were also detected. The last three compounds were tested and found to be mutagenic.

Several Cu- and Fe-hydroxide containing catalysts, supported on oxide carriers, were prepared to accelerate the removal of UDMH from aqueous solutions via oxidation by hydrogen peroxide and/or air oxygen [620]. The Cu-containing samples as well as Fe/ZSM-5 zeolites were the most active catalysts in this reaction. The reaction products were analyzed by GC and UV-visible spectroscopy. The type of oxidizer and catalyst, pH, and temperature applied had a pronounced effect on both the reaction rate and product composition.

A study of the oxidative degradation treatment of UDMH-containing wastewater using a combined UV-Fenton process revealed that the degradation rate of UDMH can reach 99% and the COD removal rate can reach 95.8% after 54 minutes at room temperature when the initial concentration of UDMH in wastewater was 400 mg/L. The added quantity of 30%  $\text{H}_2\text{O}_2$  was 102 g/L, pH value of the system was adjusted to 3.5, and 1.26 g/L of  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$  was added as the catalyst [621]. A 50% excess of hydrogen peroxide above the stoichiometrically required amount of  $\text{H}_2\text{O}_2$  was used for these experiments [622].

A Fenton's reagent process was applied to oxidize UDMH wastewater [623]. The removal efficiencies of COD in wastewater were the main indicators of reaction completion. The rate and completion of degradation of UDMH and DMA and FDMH, which were important intermediate products at different pH levels, were measured. Results showed that the degradation of UDMH and FDMH was best at pH = 3 and the removal efficiencies of COD were 91.6 and 80%, respectively. In contrast, the degradation of

DMA was best at pH = 9 and the removal efficiency of COD was 88%. The efficiency of Fenton's reagent as an oxidant can be enhanced by UV illumination, ultrasonic agitation, or microwave heating.

A potassium permanganate-hydrogen peroxide mixture has been used for the decontamination of UDMH-contaminated wastewater. The reaction products of UDMH with potassium permanganate were analyzed using GC/MS [624]. At low UDMH concentrations (<1 mg/mL), the reaction is without toxic by-products, but at high UDMH concentrations (~1 g/L), NDMA forms as a toxic by-product. The decontamination of aqueous solutions with significant UDMH concentrations (up to 1 g/L) with potassium permanganate alone or in combination with hydrogen peroxide reduced the UDMH concentration to a safe level. However, the UDMH transformation products, including the extremely toxic NDMA, accumulated in the solution.

UDMH-containing wastewater can be treated by a combined microwave-Fenton process [625]. The effects of variables such as microwave power, the dosage of the  $\text{H}_2\text{O}_2$ , the pH level, and the  $(\text{Fe}^{2+}):(\text{H}_2\text{O}_2)$  ratio on the wastewater treatment efficiency were measured. The wastewater treatment efficiency using the microwave-Fenton process was compared with efficiency when using a microwave- $\text{H}_2\text{O}_2$  method, water- $\text{H}_2\text{O}_2$  method, and water-Fenton method. The results revealed that the treatment efficiency of the microwave-Fenton process is better than the other three methods. Under the effect of microwave radiation,  $\text{H}_2\text{O}_2$  decomposes and releases  $\cdot\text{OH}$  free radicals. Thereby it can increase the efficiency of UDMH destruction by  $\text{H}_2\text{O}_2$  and reduce the negative impact of pH value on the Fenton reaction.

A special way to use hydrogen peroxide for the destruction of organic contaminants in wastewater is the Fenton's reagent, which is hydrogen peroxide with solutions of iron(II) salts. The chemistry of this reaction has already been described in this chapter. The  $\text{Fe(II)}/\text{H}_2\text{O}_2$  Fenton process was applied to oxidize UDMH in wastewater with high UDMH concentrations [626]. The results showed that when the initial pH value was 3,  $\text{Fe}^{2+}/\text{H}_2\text{O}_2$  molar ratio was 1:10, the reaction temperature was 313 K (40 °C), the degradation of UDMH in the wastewater (1000 mg/L) after 120 minutes was better than 98%, and the removal of COD was better than 96%. It was thus shown that the Fenton process was efficient in the treatment of UDMH wastewater with high concentrations.

A three-component metal catalyst was prepared and used in the process of catalytic wet peroxide oxidation (CWPO) for the decontamination of UDMH in propellant wastewater with  $\text{H}_2\text{O}_2$  [627]. The catalyst was structurally characterized using SEM, XRD, XPS, and EDAX, and its catalytic activity was evaluated using indexes such as the efficiency of UDMH degradation and COD removal and the concentrations of ammonia, formaldehyde, total nitrogen, total organic carbon, and NDMA. The reaction system was monitored using UV-Vis full wavelength scanning spectroscopy and liquid chromatography-mass spectroscopy (LC-MS). It was observed that the degradation mechanism led to  $\cdot\text{OH}$  free radicals attacking the amino group in UDMH with the simultaneous transformation of the active component  $\text{Cu(II)}/\text{Cu(I)}$ . Based on investi-

gation of the effects of reaction variables ( $\text{H}_2\text{O}_2$  dosage, temperature, catalyst dosage, pH, and the initial concentration of UDMH) on the rate of removal of NDMA, the optimal conditions for CWPO with a three-component metal catalyst were determined. The highest treatable concentration of UDMH (500 mg/L), rapid rate of UDMH removal, good reusability with a high efficiency of UDMH degradation and COD removal (99.9% in 10 minutes and 94.6% in 30 minutes, respectively), and the low concentration of NDMA by-products are all advantages of this catalyst system with  $\text{H}_2\text{O}_2$ .

A CWPO combined with a VUV irradiation process was developed for the purpose of mineralizing the UDMH in wastewater, especially to decompose all of the main by-products of UDMH decomposition, which is NDMA in this instance [628]. A CuO-NiO-MgO/ $\gamma\text{-Al}_2\text{O}_3$  catalyst was used.  $\text{H}_2\text{O}_2$  was the source of  $\cdot\text{OH}$  free radicals. UDMH degradation efficiency, COD removal efficiency, and the concentration of NDMA were measured to obtain optimal conditions, including operating parameters such as the initial UDMH concentration, catalyst dosage, initial pH,  $\text{H}_2\text{O}_2$  dosage, and temperature. The results indicated that the CWPO/ $\text{H}_2\text{O}_2$ /VUV process achieved 100% UDMH conversion efficiency, 95% COD removal efficiency, and approximately 100% UDMH removal within 30 minutes.

#### 1.6.6.3 UDMH Wastewater Decontamination Using Chlorine or Chlorine Dioxide Treatment

Chlorination of MMH or UDMH yielded significant quantities of chloromethane (methyl chloride) and small quantities of nitrogen trichloride  $\text{NCl}_3$  (it is important to note that this is a hazard if it accumulates anywhere in the system) [629, 630]. *N,N*-Dichloromethylamine, *N*-chloromethylamine, dichloromethane, and chloroform have also been detected. The potential environmental hazard of these by-products makes one-step chlorination unsuitable for the disposal of alkylhydrazines. However, chlorinolysis with simultaneous UV illumination at pH 5 is effective in destroying all types of propellant hydrazines in contaminated water [631, 632]. The ratio of UV lamp input power to reactor volume was varied from 0.1 to 0.9 W/L. Initial concentrations in the waste to be treated were 500 ppm for the three propellant hydrazines and 100 ppm for NDMA. In one series of tests in 113-L (30-gal) pilot-scale vessels it was found that UV chlorinolysis produces a much cleaner effluent than low pH chlorinolysis [633]. Excess chlorine had to be removed by treatment with sodium thiosulfate. It was also considered to keep the UV light on for several hours after the chlorine addition was stopped. This would convert some of the excess  $\text{Cl}_2$  to HCl and reduce the sodium thiosulfate requirements. Sufficient design data were obtained to scale up the process to treat 7500 L of wastewater per day.

The following products were found when treating UDMH with HTH: formaldehyde methylhydrazone, FDMH, acetaldehyde dimethylhydrazone, DMF, and tetramethyltetrazene (obviously a very complex mix of oxidation products), but no NDMA [261]. No chlorinated methanes were identified as by-products. Using more advanced GC/MS and GC/FTIR instrumentation, later investigators [295, 296] found

a mixture of 90 to 100 compounds, not all of which could be identified. FDMH was the main product. Other confirmed products were NDMA, *N,N*-dimethylcyanogen, DMF, and chloroform. In addition, acetaldehyde dimethylhydrazone and formaldehyde methylethylhydrazone were tentatively identified from their mass spectra. Since the starting products were only  $C_1$  compounds, reactions of methyl free radicals may have resulted in the formation of C—C bonds. The product distribution was very different when HTH was used. FDMH was no longer seen, but the main product tentatively identified was *sym*-1,2,3,5-tetramethyltetrazine, which is the cyclic dimer of FDMH. In continuation of that study, higher hypochlorite/hydrazine(s) ratios were applied, resulting in a lower number of reaction products and a lower concentration of the main product, FDMH. FDMH formed as an intermediate and was converted to chlorinated by-products. In one experiment, where UDMH solution was added to the sodium hypochlorite solution rather than the other way around as in most of the experiments, *N*-nitrosoethylmethylamine was found in addition to NDMA. When carbon dioxide was added to UDMH prior to the experiment, a rose color developed with the first addition of bleach, which eventually changed to yellow as the oxidation progressed. The yellow reached a maximum intensity at a point where 80% of the stoichiometric amount of hypochlorite had been added. Chloroform and NDMA were some of the more worrisome reaction products among 30 other peaks seen in the GC fractogram. In continuation of these studies, it was noted that when Aerozine-50 was treated with bleach, *N*-nitrosoethylmethylamine was prevalent, which could not be seen in identical tests with UDMH [297, 298]. It must have originated from UDMH, however, the presence of hydrazine changed the direction of the reaction. The effects of different bleach : Ae-50 ratios, lower pH (pH = 2), operating temperatures, methanol addition, and durations of standing (7 d) after bleach addition were also studied and had some impact on ultimate product compositions.

Wastewater containing UDMH was treated with chlorine dioxide and the chemical reaction mechanism was determined through analysis [634]. The wastewater was treated in a multi-stage oxidation column and an activated carbon adsorption column. Typically, the mol ratio of UDMH to chlorine dioxide was controlled between 1:9 and 1:11. Multi-stage oxidation column series were used to enhance oxidation efficiency and complete utilization of chlorine dioxide. Under the conditions of mol ratio of UDMH to  $ClO_2$  of 1:9 and an oxidation temperature of 288 K (15 °C), the treated wastewater could satisfy US local standards for wastewater discharge cleanliness.

#### 1.6.6.4 UDMH Wastewater Decontamination Using Ultrasonic Agitation

An oxidation process based on a combination of hydrodynamic cavitation and acoustic cavitation has been investigated for the decontamination of UDMH-contaminated wastewater [635]. The effects of various operating parameters such as velocity, inlet pressure, temperature, and pH on the extent of UDMH conversion have been studied with the aim of optimizing the extent of decontamination. No toxic by-products were

observed in the decontaminated samples, although the oxidation process eliminated up to 97% of UDMH. A synergistic effect has been obtained by a hybrid method of acoustic and hydrodynamic cavitation.

A pilot-scale hydrodynamic cavitation reactor, using iron metal blades as the heterogeneous catalyst, with no external source of  $\text{H}_2\text{O}_2$  was developed for the catalytic decontamination of UDMH-containing wastewater [636]. *In-situ* generation of Fenton reagents suggested an induced advanced Fenton process to explain the enhancing effect of the catalyst in the hydrodynamic cavitation process. The effects of the applied catalyst, pH of the initial solution (1.0–9.7), initial UDMH concentration (2–15 mg/L), inlet pressure (5.5–7.8 bar), and downstream pressure (2–6 bar) have been investigated. The results revealed that the highest cavitation rate of UDMH removal can be obtained at pH 3 and at initial UDMH concentrations of 10 mg/L. An increase in the inlet pressure would lead to an increase in the extent of UDMH degradation. A downstream pressure of 3 bar resulted in 98.6% degradation of UDMH after 120 minutes of processing time. Neither NDMA nor any other toxic by-product (end product) was observed in the investigated samples. Formic acid, acetic acid, and nitromethane were identified as oxidation by-products. Hydrodynamic cavitation in combination with Fenton's chemistry can be effectively used for the removal of UDMH from water.

#### 1.6.6.5 UDMH Wastewater Decontamination Using Adsorbents

Cation ion exchange fibers were used to adsorb UDMH from wastewater [637, 638]. Adsorption behaviors were studied by using static and dynamic adsorption methods. Experimental results showed that the kinetics of adsorption of the fiber was mainly controlled by a film diffusion process. Adsorption reaction rates increased with an increase in temperature. Equilibrium data for the adsorption of UDMH were correlated by a Freundlich isotherm equation. Dynamic adsorption results showed that the UDMH adsorption rate of ion exchange fibers is greater than that of granular resins, and the fiber adsorption capacity is 3.86 times larger than that of the granular resin beads. UDMH can be desorbed rapidly with sodium chloride solution.

During the investigation of the adsorption performance of strongly acidic ion-exchange fibers for UDMH, the adsorption isotherms of UDMH on ion-exchange fibers within the temperature range of 287–318 K and the concentration range of 40–190 mg/L were in accordance with the Langmuir-type and Freundlich-type isotherm equations [639]. Equilibrium adsorption isotherms at different temperatures and isosteric enthalpy of the adsorption of UDMH indicated that the process of adsorption of UDMH on ion-exchange fibers was an endothermic process. Estimations of the isosteric enthalpy of adsorption, free energy, and entropy of adsorption indicated that there were no chemical bonds formed.

The removal of UDMH from wastewater was studied using activated carbon magnetic nano-composite powders [640]. Process parameters such as pH, adsorbent

dosage, contact time, and temperature have been optimized. More than 90% UDMH removal efficiency was obtained within 30 minutes of contact time, with 20 mg of adsorbent at pH 6 at room temperature. The adsorption behavior was evaluated based on equilibrium data using both the Langmuir and Freundlich isotherm models. It was found that adsorption data were interpreted using the Freundlich model better than Langmuir model. Additionally, the adsorption data were well described by the pseudo-second-order kinetic model. The adsorption thermodynamic parameters showed that the adsorption process is endothermic with a positive standard enthalpy of 2.74 J/mol and negative standard free energy of 29.08 kJ/mol, respectively. The standard entropy changes were  $97.56 \text{ J mol}^{-1} \text{ K}^{-1}$ .

Exchange processes for different concentrations of UDMH in ion exchange resins were studied, and exchange properties could be expressed by penetration curves [641]. UDMH ion exchange properties can be expressed by a penetration and breakthrough point curve. Major factors influencing the penetration curve are concentration, velocity of flow, and type of resin. The results showed that a type 1 resin was excellent for cation exchange work and that penetration solution was in accord with the requirement to keep UDMH concentration in effluents below 0.5 mg/L. The results showed that ion exchange resins can reduce the UDMH concentration to less than 0.5 mg/L.

Carbon nanotubes (CNTs) were modified by NaOH or  $\text{H}_2\text{O}_2$  treatment and used for the removal of low concentrations of UDMH from wastewater [642]. UDMH in solution was measured using a spectrophotometric method. Scanning electron microscopy (SEM) observation and FTIR spectra showed that the as-prepared CNTs had worse dispersing properties and the tubes were longer. After treatment with NaOH, the CNTs clusters were dispersed, and after treatment with  $\text{H}_2\text{O}_2$ , the tubes were broken up and decorated with  $-\text{OH}$ ,  $\text{C}=\text{O}$ , and  $-\text{COOH}$  groups on their surface. The adsorption experiments showed that the CNTs processed by  $\text{H}_2\text{O}_2$  had the best adsorption properties for the removal of UDMH. The second best were the CNTs processed by NaOH and the worst were the as-prepared and untreated CNTs. The adsorption isotherms at 298 K and the concentration range of 40–190 mg/L all were in accordance with the Freundlich-type and Langmuir-type isotherm equations.

The UDMH adsorption performance of multi-walled carbon nanotubes (MWCNTs) modified by NaOH was in accordance with the Freundlich-type and Langmuir-type isothermal adsorption equations within the temperature range of 296–313 K and the concentration range of 44–211 mg/L [643]. Isothermal adsorption curves at different temperatures and isosteric enthalpy of adsorption of UDMH indicated that the adsorption of UDMH on MWCNTs is an endothermic process. An estimation of the enthalpy of adsorption, Gibbs free-energy, and entropy of adsorption indicated that there are no chemical bonds formed and that the adsorption behavior was reasonably well interpreted.

#### 1.6.6.6 UDMH Wastewater Decontamination via Irreversible Absorption

It was not clear if the following decontamination method was intended for UDMH solutions or UDMH vapors in the air. It might work equally well for vapor and aqueous UDMH. The absorbent (an irreversible, expendable absorbent) was oxalic-acid-modified attapulgite [644]. Attapulgite clay was modified via treatment with oxalic acid to improve its adsorption performance for UDMH. The effect of oxalic acid concentration, solid-liquid ratio, dispersant, temperature, and activation time on the adsorption performance of the attapulgite-oxalic acid was investigated and an optimal process for modifying attapulgite by using oxalic acid was selected by experiments in a test matrix. The results revealed that the UDMH absorption rate can reach 95% with attapulgite made using a saturated oxalic acid solution, a solid-liquid ratio of 1 g : 10 mL, a temperature of 303 K (30 °C), and with an immersion time of 60 minutes.

#### 1.6.6.7 UDMH Wastewater Decontamination Using Active Sludge Processes

A biodegradation technique with aerobic active sludge was used to treat UDMH-contaminated wastewater [645]. By acclimatizing cultures of bacteria to the presence of UDMH for 60 d, the removing efficiency of UDMH in the wastewater reached 98% by active sludge treatment. The pH value, sludge concentration, temperature, stirring speed, and UDMH concentration can influence biodegradation efficiency of active sludge. The optimum conditions for UDMH degradation treatment with active sludge with an incoming concentration of  $\leq 1580$  mg UDMH/L were pH 7.0–7.5, sludge mass concentration of 1.28–1.60 g/L, temperature 298–303 K (25–30 °C), and stirring speed of 80–100 RPM.

A combined process of electrolyzed oxidizing water (EOW) and membrane bioreactor (MBR) was applied to the treatment of UDMH-contaminated wastewater, and its treatment efficiency was compared with that of MBR alone [646]. The treatment efficiency of the combined process for the treatment of UDMH-contaminated wastewater was better than that of MBR alone. When the incoming COD and UDMH concentrations were 800 to 1000 mg/L and 300 mg/L, the effluent COD and UDMH concentrations were about 55 mg/L and 0.3 to 1.5 mg/L, respectively. This is close to the requirements of the allowed discharge standard of water pollutants for space propellants established by the US government. With the MBR process by itself, the effluent COD and UDMH concentrations were about 90 and 45 mg/L, respectively. These findings were worse than the results when using the combined EOW-MBR process.

An integrated MBR was used to dispose of UDMH wastewater in a laboratory test set-up [647]. The factors affecting the efficiency of UDMH removal such as hydraulic retention time (HRT), D.O., pH, and mixed liquor suspended solids (MLSS) were studied under the following test conditions: UDMH concentration 40–50 mg/L, COD 800–1000 mg/L, pH 6.5–9.0, MLSS 6–12 g/L, D.O. 0.5–3.0 mg/L, and HRT 18–24 h. The results showed that, with an HRT of 18 h, D.O. of 2.5 mg/L, pH of 8.0, and MLSS of 10 g/L, the integrated MBR had the best UDMH degradation rate. The average one-pass re-

removal efficiency of COD and UDMH removal was 95 and 99.4%, respectively. It was found that the UDMH wastewater could be purified effectively by an MBR and, therefore, the requirements of environmental protection agencies could be satisfied.

Twenty-four different strains of UDMH-degrading bacteria were isolated from acclimated activated sludge. Among them, four strains of bacteria with better degradation efficiency were selected for further testing [648]. The compound bacterial flora was built with random combinations of the four strains of bacteria. It was found that compound bacterial flora can effectively degrade UDMH. Certain combinations could achieve 72-h degradation efficiencies higher than 94% when the UDMH initial concentration was 50 mg/L. One specific combination was chosen as a highly effective compound bacterial flora for further consideration.

A combined process of EOW and MBR was applied to treat UDMH-contaminated wastewater, and its treatment efficiency was compared with that offered by MBR alone [649]. In the combined process, the treatment efficiency of UDMH wastewater was better than with the MBR alone. When the influent COD and UDMH concentrations were 800 to 1000 mg/L and 300 mg/L, the effluent COD and UDMH concentrations (after a single pass) were about 55 mg/L and 0.3 to 1.5 mg/L, respectively. This is close to the requirements of the Chinese government discharge standard of water pollutants for space propellants. In the MBR process alone, the effluent COD and residual UDMH were about 90 and 45 mg/L, respectively, which was worse than when using the combined EOW-MBR process.

On the basis of the efficiency of UDMH-degrading bacteria preserved in the laboratory, a compound flora was built with the intention to use it when UDMH leaked into water [650]. The optimal conditions for the degradation of UDMH determined by efficiency factor experiments were as follows: temperature 35 °C, medium pH 7.2, inoculation 2%, and initial UDMH concentration 50 mg/L. Under these conditions, the highest UDMH degradation efficiency was 99.10%, and UDMH residual concentration was less than 0.5 mg/L in 72 h. All indicators of water quality met the requirements of GB1473-93 emission standards.

NDMA forms naturally in many wastewater streams. Therefore, its presence does not necessarily prove that a nearby rocket test facility has contaminated the environment. Thus industrial UDMH contamination must be reviewed with consideration given to the natural concentration of NDMA found in the environment.

#### **1.6.6.8 UDMH Wastewater Decontamination via Microwave Treatment**

A combination of microwave radiation with activated carbon catalyst was used to treat UDMH-contaminated wastewater with air [651]. The effects of radiation power, exposure time, and the activated carbon amount on UDMH removal efficiency by air oxidation were studied. The results revealed that with 100 mL of 400 mg/L UDMH wastewater, radiation power 462 W, activated carbon 5.0 g, and with a reaction time of 15 minutes, the removal efficiency was only 40% under optimal conditions.

#### 1.6.6.9 UDMH Wastewater Decontamination Using Aeration

The cheapest oxidizer for the decontamination of UDMH-contaminated wastewater is air. Bubbling air through the water to maintain saturated oxygen conditions will oxidize UDMH. However, the air will also carry away some UDMH and toxic degradation products and escaped UDMH vapors may require additional secondary treatment.

The oxidation of the aqueous solutions of UDMH in the presence of Cu-, Fe-, Co-, and Mn-containing catalysts supported on oxide carriers is potentially useful as pre-treatment for the disposal of UDMH rinse waters (to conserve more expensive oxidizers needed for complete detoxification) [254]. The main products of the reaction were hydrazones and formazane, which themselves are toxic. The autoxidation of UDMH in an aqueous solution by air can be accelerated by catalysts deposited on activated charcoal [652].

An investigation into the possibility of using atmospheric oxygen as an oxidant for the full catalytic oxidative breakdown of UDMH (“heptyl”) in the natural waters of high altitude areas in the Altai/Sayan Mountains region (where the detachable portions of second-stage launchers fall down) revealed that the aerobic oxidative breakdown in the presence of copper-bearing and iron-bearing zeolite catalysts of ZSM-5 structures is an effective method for ensuring full mineralizing of UDMH, whose content in water near impact sites may be up to 1000 times the limit usually considered safe [653].

#### 1.6.6.10 UDMH Wastewater Decontamination Using Electrolyzed Oxidizing Water

Electrolyzed Oxidizing Water (EOW) can be made via electrolysis of diluted sodium chloride solutions in an electrolysis chamber with membrane separation, with free chlorine as the major oxidizing agent but also using hypochlorous acid or hypochlorite (depending on the pH level). EOW is widely used for the disinfection of food preparation equipment and even for disinfecting some food items also. EOW can be used for wastewater treatment. In addition to chlorine and hypochlorous acid, it may also contain ozone, but no hydrogen peroxide, depending on the amount of available chloride [654].

A study of the role of acidic EOW on the decontamination of UDMH-contaminated wastewater found that the UDMH removal efficiency can reach 94.8% when the volume ratio of wastewater containing an initial UDMH mass concentration of 150 mg/L to acidic EOW is 1 : 4, and when the reaction time is 1.5 minutes and the reaction temperature is  $\geq 292\text{ K}$  ( $\geq 19^\circ\text{C}$ ) [655, 656].

#### 1.6.6.11 UDMH Wastewater Decontamination via Electrolysis

Hydrazine and/or UDMH in wastewater in the concentration range of 100 to 800 ppm can be destroyed via direct electrolysis with a stainless steel cathode and a carbon, lead, or nickel anode [657]. Disodium hydrogen phosphate was added to increase conductivity and pH was adjusted with phosphoric acid.

#### 1.6.6.12 UDMH Wastewater Decontamination Using Electrodeionization (EDI)

EDI is a process that combines electrodialysis and ion exchange. An EDI device packed with strong acidic cation ion-exchange fibers was used to decontaminate simulated rocket launch site UDMH-containing wastewater under laboratory conditions [658]. The concentration of UDMH in contaminated water can reach over 3397 mg/L. The characteristic curves of voltage versus current, pH value of the water, and the effect of treating simulated water samples were studied. The results revealed that, in comparison with electro-dialysis (ED), the efficiency of water treatment using EDI was higher and the polarization of water in membrane piles mainly occurred on anion exchange membrane surfaces. The treated water after passing through the apparatus several times can reach emission standards/maximum allowable limits.

#### 1.6.6.13 UDMH Wastewater Decontamination Using Supercritical Water

The catalytic wet oxidation of UDMH in wastewater was investigated in a trickle-bed reactor system with a catalyst at 473–523 K (200–250 °C), 5.07 MPa (50 bar), and LHSV 1.8–2.3 [659]. The ratio of the oxygen-supply to COD was 2.0 and 3.0 and the initial concentration of UDMH was 0.5 to 2.0 mass-%. Experimental results showed that the UDMH concentrations could be reduced rapidly to less than 1 ppm in 26 minutes at 503 K (230 °C) or higher. A liquid-phase catalytic oxidation process was carried out continuously for 223 h and no deactivation of the catalyst was observed during this operating period.

A series of tests on the treatment of UDMH wastewater by supercritical water oxidation showed that the process with O<sub>2</sub> as the oxidant can efficiently oxidize and destroy UDMH [660]. Reaction temperature, pressure, and residence time were the main variables affecting the rate of degradation of UDMH. Increasing the reaction temperature, pressure, and prolonging the residence time can significantly augment the removal rate of UDMH. With a reaction temperature of 823 K (550 °C) at a pressure of 30 MPa and with a residence time of 90 s, the removal rate of COD was over 99.8%.

A study of supercritical water oxidation of UDMH in a tubular continuous-flow reactor system with H<sub>2</sub>O<sub>2</sub> as the oxidant, at a temperature range between 753 and 823 K (480 and 550 °C) and at a pressure of 30 MPa, revealed that the oxidative destruction of UDMH can be done quickly with a high COD removal speed up to 93.5% within 5.8 s at 823 K (550 °C) and 30 MPa on the condition that excess oxygen is available [661]. The oxidative UDMH destruction efficiency and COD removal efficiency significantly improved as reaction temperature and residence time increased. The experiments also showed that within the temperature range of 753 to 823 K (480 to 550 °C), the COD removal efficiency was strongly temperature-dependent. At 753 and 823 K (480 and 550 °C), 30 MPa, and with a 50% H<sub>2</sub>O<sub>2</sub> excess, the reaction can proceed in 1.13<sup>th</sup> order with COD and 0.29<sup>th</sup> order with oxygen. The activation energy was 44.65 kJ/mol with an Arrhenius pre-exponential factor of  $4.93 \times 10^3$ .

The catalytic oxidation of UDMH in supercritical water was investigated using  $\text{CuO}/\gamma\text{-Al}_2\text{O}_3$  and  $\text{MnO}_2/\gamma\text{-Al}_2\text{O}_3$  as catalysts and  $\text{H}_2\text{O}_2$  as an oxidant in a packed-bed flow reactor [662]. The results indicated that  $\text{CuO}$  and  $\text{MnO}_2$  catalysts have the desired effects of accelerating the UDMH disappearance. The higher rate of UDMH removal was obtained at higher temperatures and higher pressures and had a longer residence time. A 99% removal of COD was achieved at 24–26 MPa and 673–723 K (400–450 °C) within a few seconds. The catalytic effect of the catalyst  $\text{CuO}/\gamma\text{-Al}_2\text{O}_3$  was better than that of  $\text{MnO}_2/\gamma\text{-Al}_2\text{O}_3$ . The final products were  $\text{N}_2$ ,  $\text{CO}_2$ , and  $\text{H}_2\text{O}$ .

Hydrothermal processing is an alternative destruction method for hazardous waste, however, the kinetics of the reactions in the high-temperature/high-pressure aqueous environment is generally unknown. The catalytic oxidation of UDMH in supercritical water was investigated over an  $\text{Mn}^{2+}$  oxidation catalyst and with  $\text{H}_2\text{O}_2$  oxidizer in a tubular continuous-flow reactor at 24–30 MPa and 673–773 K (400–500 °C) [663]. A study of the effects of temperature, pressure, residence time, and concentration of oxidant on the destruction of UDMH indicated that UDMH can be decomposed efficiently by catalytic supercritical water oxidation. The elimination efficiency of UDMH was significantly improved as reaction temperature, pressure, residence time, and oxidant/ $\text{Mn}^{2+}$  concentrations were increased. With an  $\text{Mn}^{2+}$  concentration of 30 mg/L, the destruction of UDMH was much faster than without catalyst. A 99.6% COD removal was achieved at 30 MPa, 773 K (500 °C) and with an  $\text{Mn}^{2+}$  concentration of 30 mg/L in only 3.6 s (see also [664]).

#### 1.6.6.14 UDMH Wastewater Decontamination via Reduction

Destroying UDMH by reduction instead of oxidation avoids the formation of NDMA and other unwanted oxidation products. UDMH in UDMH-contaminated wastewater can be destroyed via catalytic reduction with Raney nickel Ni/Al alloy in alkaline solution [582, 665]. This is done with >99% efficiency at pH 13 and 313 K (40 °C). All results indicated that Ni/Al hydrogenolysis of UDMH is a reliable, quantitative, and efficient degradation method.

UDMH wastewater was treated via reduction in the presence of a Raney catalyst that was made from an Al-Ni alloy. The results showed that the optimum conditions (removal of >99% of the UDMH) for the removal of UDMH is a temperature of 313 K (40 °C), a pH of 13, and a reaction time of 50 minutes [666].

Dilute aqueous solutions of UDMH, NDMA, or *N*-nitrodimethylamine (DMNM) can be decomposed by catalytic reduction with nickel-aluminum (Ni-Al) alloy under basic conditions [574, 667, 668]. Alkylhydrazines and common contaminants or partial oxidation products, including NDMA and DMNM, are reduced to ammonia and/or aliphatic amines. The reaction is based upon dissolution of Al from the Ni-Al alloy in aqueous media to form aluminum ion and hydrogen gas. The resulting finely-divided nickel catalyzes the reduction of the hydrazine, nitrosoamine, and/or nitroamine using the hydrogen produced. Greater than 99% of propellants contained

in dilute UDMH, NDMA, and DMNM aqueous solutions were decomposed when reacted with Ni-Al alloy in 0.5M sodium hydroxide. The major reaction products were simple amines. UDMH, NDMA, and DMNM were reduced to DMA and ammonia. UDMH was an intermediate in the reduction of NDMA. NDMA, and UDMH were intermediates in the reduction of DMNM. Control experiments with Al powder rather than Ni-Al alloy showed no effect on UDMH, whereas NDMA and DMNM were reduced to UDMH, which is where the reaction stopped. Spill pillows containing Ni-Al alloy and solid sodium hydroxide were also tested and found to be effective in the absorption and decomposition of UDMH. These results showed that reductive decomposition of UDMH, NDMA, and DMNM is a promising method for propellant hydrazine waste treatment and spill control.

UDMH aqueous solutions can be decontaminated by passing the heated mixture with excess hydrogen gas through a catalytic reactor, forming DMA and ammonia [572, 573]. The ammonia can then be dissociated; the hydrogen thus formed is fed back into the first reactor. The apparatus can be built on skids so that it can be transported to remote sites where surplus UDMH can be destroyed.

#### 1.6.6.15 UDMH Destruction Using an ICP Torch

An ICP torch generates extremely high temperatures that are suitable for the destruction of most hazardous chemicals, including chemical warfare agents. The PERC<sup>TM</sup> process used an ICP torch as the heat source for a reaction chamber system to convert wastes into by-products in a safe and environmentally clean manner [577, 578]. This would be an extremely energy-expensive way of getting rid of UDMH-contaminated wastewater. UDMH wastewater can be fed together with steam into the plasma discharge where they would be converted to CO and H<sub>2</sub> along with N<sub>2</sub> and a trace of NO<sub>2</sub>.

#### 1.6.6.16 Photocatalytic Decontamination of UDMH-Containing Wastewater

A study of the photocatalytic degradation of UDMH in TiO<sub>2</sub> + Cu<sup>2+</sup> suspensions with sunlight or UV-light indicated that the best performance can be achieved by using a Cu<sup>2+</sup> concentration of 40 mg/L, providing intense UV-light, adding some H<sub>2</sub>O<sub>2</sub>, and increasing the area : volume ratio of the reactor [669]. The main degradation products of UDMH can also be oxidized so that ultimately only inorganic destruction products remain.

A combination of ozone-ultraviolet-activated carbon photo-oxidative technology for sewage treatment was used for the destruction of UDMH in wastewater [670].

Pure ZnO and Nd-doped ZnO were tested as photocatalysts for the destruction of UDMH in wastewater [671, 672]. The oxide samples were characterized by means of XRD, EDAX, UV-Vis spectroscopy, and high-resolution transmission electron microscopy. The photocatalytic performance of different ZnO particles for the destruction of UDMH was studied using a 15-W UV lamp as the light source for illumination.

The effect of the amount of Nd dopant was investigated. The results indicated that Nd-doping improved the photocatalytic performance of ZnO, and that the most active  $\text{Nd}_2\text{O}_3/\text{ZnO}$  mol ratio was 0.025. At 303 K (30 °C), the degradation rate of UDMH, starting with a contaminant concentration of 0.1 g/L, could reach 92% in 100 minutes.

A combination of artificial UV and natural sunlight is effective in destroying UDMH with hydrogen peroxide, using supported  $\text{TiO}_2$  as a catalyst, and by adding  $\text{Cu}^{2+}$  and  $\text{H}_2\text{O}_2$  [673]. With UV light illuminating a 1500 mg/L UDMH solution for 0.5 h, followed by exposure to sunlight for 7 d, the degradation efficiency was 99.9%. This leads to an energy saving. Additionally, the processing period is shortened by this method compared with natural degradation using sunlight alone.

The nano-size particles of ZnO are active as catalysts for the photocatalytic degradation of UDMH in wastewater [674]. The nano-particles of ZnO used for this purpose were characterized by means of XRD and IR absorption spectroscopy, and the effects of the operating variables, including temperature, pH, and catalyst concentration on the rate of UDMH destruction in wastewater were measured.

Nano-size particles of titanium dioxide prepared by the sol-gel method are active as photocatalysts for the photocatalytic degradation of UDMH in wastewater [675].  $\text{TiO}_2/\text{glass}$  films have been prepared using a sol-gel method starting with titanium tetrabutoxide as the precursor. The films were placed in a photoreactor designed to degrade UDMH in water [676, 677]. The photodegradation followed first-order kinetics. The results indicated that the stationary film had higher catalytic activity during the photodegradation of UDMH and longer useful life in comparison to suspended  $\text{TiO}_2$  powders that were previously used.

An initial concentration of 400 mg UDMH/L in wastewater was destroyed within 30 minutes at pH 7–8 by stirring and UV illuminating with solid superacid  $\text{SO}_{2-4}/\text{TiO}_2\text{—Cu}^{2+}$  and  $\text{SO}_{2-4}/\text{TiO}_2\text{—Ag}^+$  catalysts that had been prepared by a sol-gel method. The removal efficiency was better than 96% [678].

$\text{ZnO}/\text{Pd}$  nano-particles were used in the UDMH wastewater decontamination using photocatalysis under UV-light and sunlight [679]. Results revealed that the UV absorption property was enhanced by doping with Pd; this spanned 400–800 nm in visible light. The maximum degradation rate of UDMH in contact with  $\text{ZnO}/\text{Pd}$  for 2 h was 80% in sunlight and 77% under UV-light. The disappearance of the photocatalytic intermediate product under different light sources was analyzed. It was found that the intermediate product decomposed more quickly and thoroughly under sunlight, with a COD degradation rate of 75%. This was better than under UV-light with a degradation rate of only 58%/2h.

Experiments revealed that the photocatalytic degradation efficiency using activated carbon fiber (ACF) supported solid super acid catalysts.  $\text{H}_2\text{O}_2$  were significantly superior to those using granular activated carbon (GAC) supported catalysts [680, 681].

The photocatalytic destruction of UDMH works not only in water but also with UDMH vapors in air [682]. Carbon dioxide, water, nitric acid, and nitrogen were detected as the ultimate photocatalytic oxidation products of UDMH. Adsorbed  $\text{N}_2\text{O}$  species were detected as the main surface intermediates. The formation of NDMA was not observed. Long-term experiments to determine the photocatalyst stability in photocatalytic oxidation of UDMH showed that the catalyst exhibited stable performance. The rate of deactivation was low due to the transformation of nitrogen (mainly to  $\text{N}_2$ ). Only 10% of UDMH's nitrogen was transformed to  $\text{HNO}_3$  in adsorbed form.

### 1.6.7 Filtration of UDMH-Contaminated Air

The air in UDMH vapor contaminated areas following a leak or a controlled disconnect of transfer lines may have to be filtered and purified before personnel are allowed to enter the area again without wearing whole-body personnel protection ensembles. Air filtration installation apparatus could be like over-sized personal gas masks with consumable filters that must be exchanged periodically when their absorption capacity is exhausted. Air would be recirculated through these filters by forced flow until the UDMH concentration has been lowered to a safe level. Air-oxidation of adsorbed UDMH on the surface of the absorbent in the filter would be desirable as long as it does not result in oxidation products (e.g., NDMA) that are more toxic than UDMH itself. Air filtration installations might be similar to vented gas scrubbers described in the following section.

It was not clear if the following decontamination method was intended for UDMH solutions or UDMH vapors in air. It might work equally well for vapor and aqueous UDMH. The absorbent (one that is irreversible and expendable) was oxalic-acid-modified attapulgite [644]. Attapulgite clay was modified via treatment with oxalic acid to improve its adsorption performance for UDMH. The effect of oxalic acid concentration, solid-liquid ratio, dispersant, temperature, and activation time on the adsorption performance of the attapulgite-oxalic acid was investigated, and an optimal process for modifying attapulgite by using oxalic acid was selected using an orthogonal experiment. The results revealed that the UDMH absorption rate can reach 95% with attapulgite made using saturated oxalic acid solution, a solid-liquid ratio of 1g:10mL, a temperature of 303K (30°C), and an immersion time of 60 minutes.

It is known that biodegradation of hydrazines in soil is aided by certain types of bacteria and nutrients. It has been proposed to build a stationary air filter consisting of an incubator with permeable soil where UDMH vapors would be absorbed and digested by bacteria [683].

### 1.6.8 UDMH Absorption from Vented Pressurant Gases

Transfer of small quantities of UDMH or UDMH blends is usually achieved by pressurization of the supply tank instead of pumps. After the transfer is complete, the pressurant gas, which is saturated with UDMH vapor, must be vented. In cases where the pressurant gas cannot be safely vented to the ambient atmosphere, the pressurant gas may have to be passed through a scrubber where the UDMH is adsorbed to a solid adsorbent or washed out in a spray or trickle bed tower with an absorbent liquid. The pressurant gas is an inert gas (nitrogen or helium) and some of the vapor neutralization schemes described in the previous section for the removal of UDMH vapors from the air would not work in the absence of oxygen.

### 1.6.9 Personnel Protective Equipment for the Handling of UDMH

A carefully planned approach to workplace safety is required to protect workers from the adverse effect of UDMH inhalation [684, 685]. This includes proper protective equipment, thorough personnel training, and periodical physical exams.

Mine Safety Appliance Company's Rocket Propellant Canisters, Model GMN-SSW, were tested in gas masks against  $\text{NO}_2$  and UDMH [686]. Canisters manufactured in 1967 were compared to canisters made in 1971. Results of the study indicated that there was no statistically significant difference between the absorbing capacities of the new and old canisters for both contaminants. One of the built-in safety features of the canisters was a small viewing window containing a color indicator that changed from orange to blue-green when the absorbing capacity was 50 to 75% exhausted. The concentration  $\times$  time product to cause a color change and to penetration at an inlet concentration of 1 ppm of UDMH and a flow rate of 38 L/min. was tested. It varied between 125000 and 212000 ppm  $\times$  min., but the color would change before that point. The study concluded that indicators on the new canisters were unsatisfactory for both UDMH and  $\text{NO}_2$ .

Several polymeric materials for gloves, boots, aprons, and splash shields were evaluated in permeation tests with UDMH, MMH, and IRFNA [687–689]. Of the 28 gloves tested, butyl (0.33–0.81 mm thick) and supported neoprene (1.4 mm) were found to have the lowest permeability for UDMH during a 90-minute test.

## 1.7 Safety Properties of UDMH

### 1.7.1 Flash Point and Limits of Flammability of UDMH

A very useful source for UDMH safety information and Ae-50 is the three-volume series called *Hazards of Chemical Rockets and Propellants*; a handbook published by the former Chemical Propulsion Information Agency (CPIA). Volume 1 discusses safety, health, and the environment [690]. Volume 2 discusses solid propellants (which have not yet been discussed in this publication), and Volume 3 discusses liquid propellants

[691]. NASA's WSTF has put together a very practical handbook called the *Ignition and Thermal Hazards of Selected Aerospace Fluids* (which includes UDMH and Ae-50) [692].

### 1.7.2 Flash Point of UDMH in Air

The flash point of UDMH in air is 257 K [200]. In the same report, the flash points of UDMH mixtures called MAF-1 and MAF-3 were determined to be 275 and 295 K, respectively.

### 1.7.3 Auto-Ignition Temperature of UDMH in Air

The auto-ignition temperature of UDMH in air (0.1 mL squirted into a 125-mL Pyrex round flask or 0.3 mL squirted into a 1-L Pyrex round flask) was 507 K (454 °F) [177]. This temperature did not change much by adding 40% DETA to UDMH (516 K = 469 °F). This fuel blend is also known under the name U-DETA. Similar experiments were conducted in inert gases instead of air to determine the autodecomposition temperature of UDMH in the same apparatus.

The critical conditions of pressure and temperature and composition (critical limits) necessary for UDMH explosion have been measured and the effects of vessel surface, vessel diameter, and inert diluents on the critical limits were investigated [199]. The spontaneous ignition limit found for the decomposition of pure UDMH satisfied the criteria of a thermal explosion. The overall activation energy  $E_a = 117 \pm 4 \text{ kJ/mol} = 28 \pm 1 \text{ kcal/mol}$  derived from the measured ( $P$  versus  $T$ ) limit by the application of thermal explosion theory agreed with that derived from kinetic investigations of the slow decomposition. By contrast, spontaneous ignition in oxidative combustion is extremely complex and differs qualitatively as well as quantitatively from the superficially analogous combustion mono-, di-, and tri-methylamines. There are four distinct oxidation regimes: slow reaction, chemiluminescent oxidation, weak ignition, and strong explosion. In addition to this, multiple ignitions have been observed. The autodecomposition of UDMH in a glass vessel started at 693 K/6.4 kPa = 420 °C/48 mm Hg, 718 K/3.9 kPa = 445 °C/29 mm Hg, 758 K/1.6 kPa = 485 °C/12 mm Hg, or 787 K/0.8 kPa = 514 °C/6 mm Hg. In each case, the pressure rose to twice the initial pressure as the result of the decomposition of the UDMH vapor.

It was noted that UDMH has a lower autodecomposition temperature than hydrazine (703 versus 873 K at 8 kPa = 60 mm Hg). Additional data on the spontaneous ignition of UDMH in the air were obtained in a 350-cm<sup>3</sup> silica vessel at 6.45, 3.84, 1.65, and 0.76 kPa (48.5, 28.9, 12.4, and 5.7 mm Hg), resulting in auto-ignition temperatures of 693, 720, 757, and 787 K, respectively [693]. If the logarithm of the test pressure was plotted against the reciprocal absolute temperature of auto-ignition, a straight linear (Arrhenius-type) relationship could be observed that was suitable for data interpolation.

In another USBM spontaneous ignition test apparatus in air, UDMH ignited at 523 K (482 °F) with a delay of 12 s [178]. At an elevated pressure (1.38 MPa =

**Figure 19:** Time lag of UDMH ignition in air in a 200-mL Pyrex flask at 1 atm pressure as a function of spontaneous ignition temperature. (Reproduced and modified from [178].)

200 psig), the ignition temperature was lowered to 421 K (298 °F) and the ignition delay was markedly shorter (1 s). Figure 19 shows the time lag of UDMH ignition in air in a 200-mL Pyrex flask at 1 atm pressure as a function of spontaneous ignition temperature. The sample volume varied between 0.05 and 0.14 mL of UDMH. No ignitions were observed below 523 K (250 °C). If one plots the logarithm of ignition delay versus reciprocal absolute temperature, the slope of the curve indicates an activation energy of 88 kJ/mol (21 kcal/mol) for the temperature range 533–573 K (260–300 °C).

One can attempt to pre-mix oxidizer and fuel first, then start the heating process. However, the difficulty frequently encountered with auto-ignition temperature-testing is raising the test temperature uniformly and quickly without triggering premature slow reactions in the gas phase. Some ignition reactions also show an inhibition period, causing a delayed ignition a long time after the test temperature has been

reached. This has also been observed with hydrazine and with UDMH in closed vessels at low pressures.

Minimum ignition energies measured using laser-induced breakdown in the air/UDMH mixtures were compared to those of more common flammable mixtures such as air/hydrogen and air/hexane [694]. Seeding the mixture with  $\text{CO}_2$  enhanced the absorption of radiation from the  $\text{CO}_2$  laser.

### 1.7.3.1 Auto-Ignition Temperature of UDMH in Other Atmospheres

The chapter on methylhydrazine already contains discussions about the spontaneous auto-ignition of MMH in air and how that contains varying amounts of  $\text{NO}_2$ . Additionally, the conditions leading to the accidental ignition of such mixtures and tabulated spontaneous ignition data for all three hydrazines ( $\text{N}_2\text{H}_4$ , MMH, and UDMH) have already been discussed in the MMH section.

Figure 20 illustrates the spontaneous ignition temperature of UDMH vapors as a function of fuel vapor concentration in air- $\text{NO}_2$  atmospheres with varying  $\text{NO}_2$  concentrations [237].

**Figure 20:** Spontaneous ignition temperature of UDMH in  $\text{NO}_2$ /air mixtures at 298 K as a function of UDMH concentration. (Reproduced and modified from [237].)

A statistical evaluation of 600 ignition tests, where liquid UDMH was injected into atmospheres containing increasing amounts of  $\text{NO}_2$  at 298 K, resulted in the probability curve shown in Figure 21.

**Figure 21:** Probability of ignition of liquid UDMH on contact with  $\text{NO}_2$ /air mixtures at 298 K as a function of  $\text{NO}_2$  concentration. (Reproduced and modified from [237].)

It is unlikely that UDMH would be in contact with pure oxygen and thus auto-ignite, except maybe at the launch sites of the Glushko RD-119 engine at one point in time. This was used in the second stage of the Russian KOSMOS launcher, and in some IRBMs and used LOX/UDMH in an O:F mass ratio of 1:5. For the laboratory study of ignition mechanisms, it is better to work with pure oxygen and to eliminate the effects of nitrogen in the air as the diluent. The critical pressure limits of the spontaneous ignition of UDMH in oxygen were determined by measuring the total pressure of the reaction mixture necessary for ignition on admission to a hot vessel [693]. Distinct modes of oxidation exist for UDMH undergoing spontaneous ignition both in decomposition and in oxidative combustion, including strong explosions, weak ignition, chemiluminescent oxidation, and slow reaction. When studying the ignition behavior of UDMH-oxygen mixtures on rapid admission to a pre-heated quartz vessel, it was found that the explosion limits of oxygen-UDMH are far more complex than those of oxygen-hydrazine. At least five different modes of reaction were observed: chemiluminescence ("cool flames"), weak ignitions, multiple ignitions, slow reaction, or vigorous explosion. The spontaneous ignition pressure limits at two different temperatures

(787 and 693 K) were determined and plotted in a total pressure versus percent UDMH diagram. In this type of graphical illustration, the different regimes of ignition were separated by fairly sharp borderlines. The minimum pressure at which strong explosions could be observed (12–15 mm Hg) occurred at a composition close to  $(\text{CH}_3)_2\text{NNH}_2 + 2\text{O}_2$ . All data of pressure and temperature dependence of the explosion limit were in agreement with those expected from a thermal explosion theory. The combustion of UDMH in oxygen showed hardly any similarity with that of chemically similar looking methylamines. Qualitatively, the combustion of UDMH differed markedly from that of the superficially analogous mono-, di-, and tri-methyl-amines. Depending on the pressure, composition, and temperature, oxidation of UDMH in oxygen may be either **(1)** a slow reaction, unaccompanied by light emission, **(2)** a very feebly chemiluminescent reaction, **(3)** a weak ignition, or **(4)** a violent, audible explosion accompanied by an intense flash. Furthermore, there are possibilities of multiple ignitions with reactions **(3)** and **(4)**. Complete oxidation of UDMH with oxygen is very exothermic:

Vigorous explosions were encountered in all mixtures from 15 to 45% UDMH, with the critical pressure limit tending to be a minimum near the center of this composition range. The weak ignitions were observed in mixtures that were either too rich or too lean in UDMH for strong explosions to occur. The chemiluminescent reaction was seen (under conditions too mild for strong explosion or weak ignition) in mixtures containing from 14 to 62% UDMH. Chemiluminescence appeared not to be a precursor of ignition. The composition dependence of the pressure limits for the spontaneous ignition of  $\text{O}_2$ /UDMH mixtures at 787 or 693 K (514 or 420 °C) was found to be a minimum at ~33%, which corresponds to a stoichiometric mixture of UDMH +  $2\text{O}_2$ , as demonstrated in Figure 22.

The variation with temperature from 787 to 573 K (514 to 300 °C) of the limiting total pressure for the explosion in a mixture of  $2\text{O}_2$  + UDMH was examined. For the undiluted  $2\text{O}_2$  + UDMH mixture, ignition pressure dropped from 5.3 kPa (40 mm Hg) at 573 K (300 °C) to 1.6 kPa (12 mm Hg) at 787 K (514 °C). Diluent gases would raise the necessary pressure for ignition by 2.7–4 kPa (20–30 mm Hg). Induction periods varying from 2 s at 626 K (353 °C) to 8 s at 573 K (300 °C) were observed to occur with some explosions.

It was noted that the addition of NO made the mixture more likely to explode (with NO acting as an oxidizer). In the slow thermal hydrazine decomposition, the addition of NO reduces the reaction rate. A similar effect was observed when mixtures of UDMH vapor and NO were sparked [695]. UDMH vapor by itself would not explode at all, but mixtures with as little as 4 kPa NO and 6.66 kPa UDMH would explode above 353 K.

**Figure 22:** Spontaneous ignition of oxygen/UDMH mixtures at 693 K (420 °C). Dependence of the pressure limit on composition. (Reprinted and modified from [693], with permission from ©1963 Elsevier; permission conveyed through RightsLink.)

#### 1.7.4 Limits of Flammability of UDMH in the Air

The limits of flammability of flammable vapors can be expressed in terms of temperature limits (similar to a flash point) or in terms of percent by volume (vol.-%). The lower temperature limit of UDMH in air was found to be 258 K (5 °F) at a pressure of 98.3 kPa (740 mm Hg). The upper limit is close to the boiling point. To maintain all UDMH in the vapor phase, additional flammability tests were conducted at temperatures sufficiently high above the boiling point. At 373 K (212 °F), the flammable range of UDMH in the air was from 69 to  $92 \pm 4\%$  by volume [178]. At 473 K the flammable range was widened from  $1.8 \pm 0.1$  to  $99 \pm 1\%$  by volume UDMH. At elevated pressure (688 kPa = 100 psig) in a 5-cm (2-in.) chamber, the lower limits at 373 and 473 K were  $2.2 \pm 0.3$  and  $1.8 \pm 0.2$  vol.-%, respectively. The upper limits during the pressure tests consisted of saturated vapor mixtures with no air (Table 16). The most sensitive mixtures for the spark ignition of UDMH vapors in air occur at 8% by volume UDMH [200].

**Table 16:** Flammability limits of UDMH at elevated temperatures.

| Pressure, atm | Temperature, °C | Lower limit, Vol.-% UDMH | Upper limit, Vol.-% UDMH |
|---------------|-----------------|--------------------------|--------------------------|
| 1             | 100             | $1.9 \pm 0.1$            | $92 \pm 4$               |
| 1             | 150             | —                        | $98 \pm 2$               |
| 1             | 200             | $1.8 \pm 0.1$            | $99 \pm 1$               |
| ~7.8          | 100             | $2.2 \pm 0.3$            | 100                      |
| 7.8           | 200             | $1.8 \pm 0.2$            | 100                      |

Data source: [178].

### 1.7.5 Minimum Ignition Energy for UDMH Vapor Ignition

Electrostatic discharge has been the cause of numerous fire and explosion accidents. The static charge carried by a person with insulating shoe soles shuffling across a synthetic fiber carpet can reach 10 kV and  $10^{-5}$  Cb, which is sufficient to ignite UDMH vapors in the air. Designers for propellant storage and transfer facilities should adhere to the recommendations provided in NFPA 77 (*Recommended Practice on Static Electricity*) [696].

The minimum ignition energy of UDMH vapor in the air was determined in a flow-through system that was better suited to high boiling liquids than the static ASTM system. The minimum ignition energy of 4.3 vol.-% UDMH vapors in the air was 2.8–3.4 mJ for two to six positive ignition events out of six tests that were attempted [697].

Minimum ignition energies measured using laser-induced breakdown in homogeneous air/UDMH mixtures were compared to those of more common flammable mixtures such as air/hydrogen and air/hexane obtained using electric discharge ignition [694]. A model for flame initiation was based on the temporal and energy density characteristics of the energy source.

In other experiments, the minimum required energy of a spark discharge with oxygen/UDMH vapor mixtures was determined at atmospheric sea level pressure, at 0.5 atm, and at 0.25 atm pressure in the I-8 apparatus test chamber. The minimum required ignition energy as a function of UDMH concentration in oxygen is illustrated in Figure 23. Only the curve at 0.25 atm pressure shows the complete U-shape with a shallow minimum at near stoichiometric composition.

NO is not a strong oxidizer, and it is not hypergolic with UDMH. The ignition of NO/UDMH mixtures can allow some comparisons to the ignition of NO<sub>2</sub>/UDMH mixtures. Pure UDMH vapor did not explode when sparked but did ignite if NO was present [695]. A small amount of NO can affect the decomposition of a much larger amount of UDMH, with the NO acting as a sensitizer. The ignition was considerably less violent than in the case of hydrazine, and there was no appreciable emission of visible light. In the NO/UDMH mixture, there exist critical upper and lower pressure limits of explosion, the region of explosion between them being widened by an increase in the initial temperature. From the results, it was concluded that dissociation of the UDMH

**Figure 23:** Stored energy from a capacitor required for the direct detonation of oxygen/UDMH mixtures (using an exploding wire in a 1-liter bomb). (Reproduced and modified from [200].)

molecule into  $\text{Me}_2\text{N}$  and  $\text{NH}_2$  radicals is an essential step in the decomposition process. At the comparatively high temperatures reached during the ignition, the  $(\text{CH}_3)_2\text{N}$  radicals do not behave in the manner previously observed at  $100^\circ\text{C}$ ; instead, they appear mainly to react with  $\text{NO}$ .

### 1.7.6 Firefighting of UDMH Fires

The extinction of water-soluble hydrazine fires is easily compared to firefighting of other commonly used fuels (gasoline, kerosene) because hydrazine and its derivatives are miscible with water. In the event of a fire, the area is best flushed with copious amounts of water until UDMH is diluted below the fire point concentration. Open-air burning tests with hydrazine and UDMH in open pans of 28-, 315-, and 2100- $\text{cm}^2$  surface areas revealed that 4.7 L of water was consumed per L of hydrazine to extinguish a hydrazine fire. In contrast, only 1.5 L of water per L of UDMH was consumed to extinguish a UDMH fire [698–701]. Hydrazine burned an order of magnitude faster than UDMH, which was due to the ability of hydrazine to burn like a monopropellant as a decomposition flame not requiring oxygen exists close to the liquid surface. The hydrogen produced by this flame then burns with air as a diffusion flame. The addition of water to the hydrazine reduced its burning rate substantially. The slower-burning UDMH had a burning rate of the same magnitude as ethanol or gasoline. Therefore, a decomposition flame was not present. Depending on the pan size, the pool burning rate of UDMH ranged from 0.22 to 0.49 cm/min. (0.088 to 0.195 in./min.). Besides

water, including water spray, potassium bicarbonate dry chemical, carbon dioxide, Halon 1301, trichlorotrifluoroethane, and foam blankets were evaluated in relation to hydrazine fires, and plain water was found to work best [200, 203, 206, 207, 702, 703].

Two parts by weight of water per part of Aerozine-50 (Ae-50) will inert an Ae-50 spill against ignition in air [205]. In a burning Ae-50 pool, the fuel evaporation rate is approximately  $49 \text{ g s}^{-1} \text{ m}^{-2}$ . A well-dispersed flow of water at  $100 \text{ g s}^{-1} \text{ m}^{-2}$  is sufficient for extinguishing a fire. A tenfold excess of water (10 kg water per kilogram of fuel) is required to inert an Ae-50 spill against hypergolic ignition with NTO. Bromotrifluoromethane (Halon 1301) can be used to inert vapor spaces or to extinguish small fires but very high  $\text{BrCF}_3$  concentrations are required (>7% by volume) and the protection is not long-lasting.

### 1.7.7 Detonability of UDMH

#### 1.7.7.1 Detonability of UDMH Liquid

In the card gap test with a 1-in. diameter  $\times$  3-in. length aluminum tube, with donor charges of one, two, and even with three tetryl pellets with zero cards for attenuation, liquid UDMH could not be stimulated to detonate at temperatures up to 308 K (35 °C) [178]. Additional tests with UDMH samples heated to 323 K (50 °C) in a 2.5-in. diameter  $\times$  6-in. length steel tube with four tetryl pellets as a donor had the same negative result. The bulging of the tube was the same as that observed after a blank test with water. In continuation of the UDMH tests, UDMH was deliberately contaminated by soaking it with various contaminants (rust, copper, brass, copper oxide, mercury) for 24 h at room temperature. The contaminated UDMH was then tested in the 2.5-in. diameter tubes. In each case, the tube bulging of the contaminated samples was the same as that with pure UDMH. Similar tests were performed with UDMH blends such as U-DETA (which is 60% UDMH + 40% DETA) and with JP-X Type I (which is 40% UDMH and 60% JP-4). Again, the tube bulging of the contaminated samples was the same as that with pure UDMH or water. In the same test series with the same test set-up, anhydrous hydrazine or methylacetylene did not detonate, ethylene oxide had a partial detonation, and nitromethane resulted in complete fragmentation of the tube into small splinters.

#### 1.7.7.2 Detonability of UDMH Vapors

The detonation velocity of low-pressure  $\text{O}_2\text{-N}_2\text{-UDMH}$  mixtures at 5.31 and 5.58 kPa (40 and 42 mm Hg) total pressure was measured as 2100–2300 m/s, which is in close agreement with predicted velocities based on the Chapman-Jouguet calculations [196]. Mixtures of dioxygen and UDMH vapor heated rapidly in a shock tube underwent rapid decomposition followed by oxidation after an ignition delay [183, 704]. An earlier section discussing the combustion of UDMH in this chapter provided additional information on oxidation reactions in shock tubes (see also [198]).

### 1.7.7.3 Bullet Impact Sensitivity of UDMH

In one series of projectile impact tests, hydrazine or UDMH were shot at while stored in aluminum, stainless steel, or titanium tanks [705]. A stainless-steel tank was made from 89-mm (3.5-in.)-diameter tubing by welding on end caps and a similar aluminum tank was made from 102-mm (4-in.)-diameter tubing. The thickness of the end caps where the impact occurred was 0.8 mm (0.03 in.) for both tests. Steel spheres (5.6 mm = 0.219 in.) were accelerated to 1763 m/s and aimed at the end caps. UDMH in a titanium tank with 0.5-mm-thick walls was impacted by the same size steel-sphere projectile at 1763 m/s. No reaction was observed between the hydrazines and the tank wall in any of the tests, in contrast to liquid oxygen which started a violent reaction in all materials tested and was perforated by bullets.

## 1.8 Toxicity of UDMH

After the phasing out of NIKE, BULLPUP, LANCE, and TITAN missiles in the 1970s, it seemed as if the use of UDMH as a rocket propellant in the US was to become a thing of the past. The initial total reliance on the Space Shuttle as the Space Transportation System eliminated the need for any more UDMH toxicity testing, after all. This changed when, after the first Space Shuttle disaster in the 1980s, the TITANs and DELTA II upper stages re-emerged as expendable launch vehicles and UDMH (Ae-50) continued to be used as a rocket propellant in the US inventory. As of 2021, UDMH even continues to be the main fuel on the Zvezda service module on the International Space Station supplied by Russia. Even non-Russian supply ships sometimes carry UDMH fuel supplies to the International Space Station. It is hoped that there will never be any UDMH accidents. Nonetheless, it is important to include all references to UDMH toxicity in this book to serve as a source of information for hazard evaluation in the design of space station facilities and in treating of patients inadvertently exposed to UDMH vapors. Launches of DELTA II second stages with Ae-50 fuel continued into 2018 but are now a thing of the past. Residual stocks of Ae-50 had to be disposed of.

UDMH is used in the synthesis of succinic acid dimethylhydrazide which is commonly known under the tradename Alar<sup>®</sup>. It was used as a growth regulator on apples until 1989 when its use on food crops was banned by the EPA following a public controversy between apple growers and environmentalists. The hydrolysis of succinic acid dimethylhydrazide may release UDMH. Both are toxic when eaten in high doses.

A summary review of the literature on the toxicity of hydrazines, including UDMH, was compiled in 1981 [706]. The health and environmental effects profile for 1,1-dimethylhydrazine is published in a summary of literature data with 79 references on hydrazine and UDMH toxicity and a closer review of animal exposure data [707]. This EPA study was done to support listings of hazardous constituents of a wide range of waste streams under Section 3001 of the RCRA. For a  $10^{-5}$  probability of contracting cancer, the human carcinogenic potency factor ( $q_1^*$ ) of UDMH derived from a series

of animal exposure experiments was  $8.7 \text{ mg (kg body weight)}^{-1} \text{ day}^{-1}$ . However, these animals were fed hydrazinium sulfate solutions in their drinking water. As such, it is still not known whether the same carcinogenic risk numbers apply to the inhalation of UDMH vapor.

Many of the UDMH toxicity studies were done with UDMH of dubious purity. Most of the UDMH used likely contained traces of NDMA and even SDMH, both contaminants that are known to cause cancers in test animals more so than pure UDMH by itself. The investigators failed to analyze the UDMH for NDMA or SDMH before starting their experiments. As such, the experiments should be repeated with UDMH that was verified to be free from NDMA, SDMH, and FDMH.

### 1.8.1 Inhalation Toxicity of UDMH

The most likely route of accidental poisoning by UDMH is through inadvertent inhalation of UDMH vapors from a leak or a propellant spill. Inhalation toxicity of UDMH and the other hydrazines was studied over several decades in animal exposure tests. Table 17 is a comparison of LC50 data for the three hydrazines in different species of test animals. Based on these data, the acute inhalation toxicity of UDMH is between that of MMH and hydrazine.

**Table 17:** Lethality of hydrazine, UDMH, and MMH in rodents.

| Test animal species | Inhalation toxicity, LC50, ppm |           |           |
|---------------------|--------------------------------|-----------|-----------|
|                     | Hydrazine                      | UDMH      | MMH       |
| Rat                 | 570 (4 h)                      | 250 (4 h) | 74 (4 h)  |
| Mouse               | 252 (4 h)                      | 172 (4 h) | 56 (4 h)  |
| Hamster             | ND                             | 392 (4 h) | 143 (4 h) |

Data source: [708].

The most comprehensive source of information on the chemistry of hydrazines contains sections on animal inhalation toxicity tests [709].

Serious concern about the safety of previously established TLV limits for UDMH arose in 1964 when it was discovered (for the first time) that continuous 90-d exposure of animals to UDMH vapor at the then valid TLV (0.5 ppm) was lethal to one out of ten monkeys, three out of 50 rats, and six out of 100 mice [710]. Although a typical TLV load would be only 8 h/d and 40 h/wk, this test demonstrated that there was only a narrow margin for safety. It was not until 1994 that the TLV for UDMH was eventually lowered by more than one order of magnitude from 0.5 to 0.01 ppm. There were no epidemiological studies that correlated the frequency of illnesses with the period when workers might have been exposed to the full TLV concentration for UDMH when it was still 0.5 ppm.

### 1.8.2 Oral and Injection Toxicity of UDMH

The most comprehensive source of information on the chemistry of hydrazines contains sections on animal toxicity tests with UDMH, where the toxicant was administered by various routes other than by inhalation [711].

A comparison of the acute toxicities of hydrazine, MMH, and UDMH (sorted by a mode of administration) has already been provided in this volume in the chapter titled "Methylhydrazine." For other reviews and summaries on UDMH toxicity, see [712].

### 1.8.3 Blood Effects of UDMH

Blood and aqueous humor samples were obtained from anesthetized dogs after applying various single doses to a 300-cm<sup>2</sup> area on the chest [713]. The application of UDMH to the skin and the subsequent absorption of UDMH into the circulating blood did not change the thrombin, overall coagulation, syneresis, maximum amplitude, or icteric values of blood coagulation. There were no changes in any of the factors that affect blood clotting associated with either dose or time elapsed after UDMH application. Contrary to the effect of hydrazine, UDMH decreased the thromboplastin generation time after 120 minutes but the amount of the decrease was not dose-dependent.

The acute toxic effect of UDMH after intratracheal intubation in rats was studied by measuring the UDMH effect on glucose metabolism [368]. The effects of UDMH on pyruvate and  $\alpha$ -ketoglutarate metabolism in rat blood were detected by UV spectrophotometry. The level of pyruvate in rat blood had a decreasing tendency, especially at 60 and 90 minutes after UDMH administration, and the level of pyruvate decreased significantly at all dose levels. The level of  $\alpha$ -ketoglutarate also decreased under the same conditions. These results suggested that UDMH disturbs glucose metabolism and energy metabolism, following which it can cause neurotoxicity.

Hemolysis is the breaking up of red blood corpuscles (erythrocytes), rendering them ineffective for the transport of oxygen. Blood cell destruction and anemia are less frequently observed after inhalation or sc injection and are only seen in severe cases of chronic poisoning. The hemolytic action among all the alkyl hydrazines is most pronounced with MMH [714] and not with UDMH [708, 715, 716].

Three individuals out of a group of chemists working with UDMH under close medical supervision developed extremely high WBCs (white blood cell counts) above 12500 without clinical evidence of infection or hemoconcentration [717]. While initially one after the other assumed the duties of their sickened predecessors, as soon as this subacute poisoning was noted in the course of bi-weekly examinations, the individuals were assigned to other duties away from UDMH exposure. Propellant transfer personnel in a UDMH tank farm, in particular a group that had high UDMH exposure during a spill, were found to have abnormal RBC (red blood cell count), WBC, casts in the urine, and abnormally positive cephalin flocculation.

#### 1.8.4 Immune System Effects of UDMH

UDMH poisoning has adverse effects on the immune system of animals [718–720].

#### 1.8.5 Nervous System Effects of UDMH

The most comprehensive source of information on the chemistry of hydrazines contains sections on nervous system toxicity tests and effects on the brain in animals with UDMH. Comparisons to the effects caused by the other hydrazines are also provided [721]. Effects of UDMH on the brain can be caused by disturbed enzyme metabolism in the brain. Hydrazine and UDMH severely inhibited glutamate (glutamic acid) decarboxylase (GAD) activity in rat brains [722–725].

#### 1.8.6 Other Toxic Effects of UDMH

Other organs affected by UDMH toxicity are the heart [726, 727], kidney [728–730], liver [731–734], skin [713, 735–739], and eyes [713, 740].

#### 1.8.7 Therapy and Prophylaxis of UDMH Poisoning and the Treatment of Accidental Poisonings with UDMH

This section contains both the results of animal tests and the accounts of the emergency treatment of human UDMH poisoning victims. In cases of human UDMH poisoning, the first expected symptom of intoxication is emesis. If therapy is carried out immediately after this first indication of a problem, there is sufficient time to prevent convulsions.

In a series of animal tests, pyridoxine therapy constituted the first successful approach to a specific treatment that prevents convulsions and death in all species tested. The ED<sub>0</sub> (effective dose) of two vitamin B<sub>6</sub> congeners, pyridoxine hydrochloride (PIN-HCl), and pyridoxamine dihydrochloride (PAM-2HCl) was determined in mice, rats, dogs, and monkeys [741, 742]. The only manifestation that was not abolished by this therapy in dogs and monkeys was vomiting. The data were the basis for the suggested emergency treatment of severely exposed personnel, consisting of the injection of 25 mg/kg PIN-HCl. The toxicity of pyridoxine itself (without UDMH), including overall therapeutic and clinical considerations with routes of administration, dosage regimens, and other supportive measures was discussed. These experiments revealed an extremely important species difference in the protective efficacy of PIN-HCl and PAM-2HCl against UDMH toxicity in laboratory animals. It appeared that the mouse and the monkey were more easily protected by PIN-HCl than by PAM-2HCl. In contrast, PAM-2HCl was approximately ten times more effective than PIN-HCl in rats. These differences were probably caused by species differences in the metabolism of B<sub>6</sub> analogues. From a practical standpoint, both PIN-HCl and PAM-2HCl did afford protection in all species, although the dose required for protection varied with the species. After the patient displays nausea and/or vomiting,

25 mg/kg PIN-HCl should be administered. In a 70-kg person, this would amount to 1750 mg or about 8 mL. Additional measures could include hydration of the patient since 30–50% of UDMH is excreted with the urine within 5–6 h.

A dose of 100 mg/kg UDMH given to dogs *i.v.* or *i.p.* caused vomiting in 30–60 minutes and clonic-tonic convulsions in 30–120 minutes. Pentobarbital, methitural, phenobarbital, amobarbital, and diphenylhydantoin failed to control seizures or prevent death. The dose of PIN-HCl necessary to protect dogs against the consequences of a UDMH poisoning with 100 mg/kg was of the order of 100 to 150 mg/kg. A smaller protective dose of 50 mg PIN-HCl was effective in protecting a group of 19 monkeys that was exposed to the same, usually fatal dose of UDMH. A combination of two vitamin B<sub>6</sub> congeners, pyridoxine, and pyridoxamine was tested as an antidote against UDMH poisoning in rats and mice. 100 mg/kg protected rats against death from a dose of  $2 \times \text{LD}_{50}$  of UDMH. In mice, a somewhat smaller protective dose of 75 mg/kg allowed the survival of 50% of the poisoned animals. Mouse and monkeys were more easily protected by PIN-HCl than by pyridoxamine hydrochloride. Pyridoxamine hydrochloride was ten times more effective in the rat. As a result of these animal tests, an injection of 25 mg/kg of PIN-HCl is recommended as emergency treatment of personnel severely exposed to UDMH.

Eighteen different compounds were tested for their therapeutic effect against hydrazine, MMH, or UDMH poisoning (*i.p.*, mice) [726]. Of those found to be effective, arginine and ornithine provided clear-cut protection from death and convulsion caused by otherwise fatal hydrazine doses. However, the two amino acids were ineffective against MMH or UDMH. Amino-oxyacetic acid or pyridoxine provided effective protection against MMH or UDMH poisoning but were ineffective against hydrazine. Only partial protection against UDMH was offered by *p*-nitrobenzaldehyde or *p*-chlorobenzaldehyde.

There have been two cases of acute accidental hydrazine-UDMH poisonings in rocket test technicians. In these cases, the timely administration of pyridoxine•HCl brought about immediate improvement of the condition of the accident victims [743, 744]. After injecting 200 mg *i.v.* and  $2 \times 200$  mg *i.m.* PIN-HCl, all nervous disorder symptoms except chest congestion vanished within 20 minutes. Another technician caught in the same leak had hyperactive reflexes, high respiration rate, and bilateral pulmonary edema. He also was given 200 mg *i.v.* plus  $2 \times 200$  mg *i.m.* PIN-HCl. His dyspnea improved and his other symptoms abated. Follow-up studies during the next days and weeks showed no permanent ill effects in any of the two patients. In another accident at the same test installation, four workers suffered severe nausea and vomiting that possibly could have been prevented by the immediate use of pyridoxine. This drug was only later administered *i.v.* at the onset of vomiting, following which the vomiting stopped in 20 minutes.

A study of the electrolyte distribution and the effects of anti-diuretic hormones after UDMH administration showed that there was no change in electrolyte excretion in the urine of rats within 2 h following UDMH administration. Nicotine tartrate re-

duced urine excretion. It was proposed that if a diuretic could facilitate UDMH removal from the animal, some of the subsequent poisoning symptoms would be reduced. Replenishing salts after strong urine loss would restore electrolyte balance. Other protective agents tested included pyridoxine, desoxypyridoxine hydrochloride, ammonium chloride, glutamic acid hydrochloride, arginine hydrochloride, choline chloride, niacin, however, only pyridoxine showed any benefit in combating UDMH poisoning [745].

Besides amino acids and amino compounds, pyridoxine (vitamin B<sub>6</sub>, PIN), pyridoxal (PAM), and pyridoxal phosphate (PAMP) were tested as antidotes against Aerozine-50 poisonings in animals [746]. Animal tests indicated that all forms of the B<sub>6</sub> vitamers were at least partially effective against the convulsive effects of the hydrazines. This clarified, to some extent, the conflicting data on the ability of PIN (but not PAM or PAMP) to prevent convulsive seizures in UDMH-treated rats. There was a relatively narrow range of effective dosages of PAM and PAMP, with amounts above or below these ranges not being effective. Thus, findings will vary and are dependent upon the dosage used.

Other tests indicated that *i.p.* pyridoxine protects rats from UDMH toxicity, while PAM and PAMP do not. When PAM and PAMP were injected immediately after UDMH, convulsions and death occurred much sooner than with UDMH alone. Similar findings with PAM and PAMP have been reported for hydrazine and several substituted hydrazines.

Pyridoxine and phenobarbital were tested as a prophylactic treatment of Aerozine-50 poisoning [747, 748]. Aerozine-50 caused a 50% mortality in rats at a dose of 120 mg/kg. A combination of pyridoxine (0.5 mmol/kg), arginine, and L-glutamate (both at 4 mmol/kg) afforded significant protection for rats that were given 130 mg Aerozine-50/kg body weight.

Large doses of pyridoxine given either prior to or after UDMH intoxication reduced the convulsant effect of UDMH in monkeys [749].

Rats were subjected to single doses of 120 mg UDMH/kg *i.p.* (which is normally the LD<sub>100</sub>) and then treated with vitamin B<sub>6</sub> [750]. Convulsions were effectively prevented by injecting PAM, PAMP, or pyridoxine directly into the brain in order to bypass the blood-brain barrier. The treatment was more effective when it was delayed until just before the onset of convulsions. PAM and its phosphate reacted with UDMH, leaving little coenzyme available for metabolic functions at distant sites. Pyridoxine, however, provides a B<sub>6</sub> reservoir that does not form a UDMH hydrazone, allowing replenishment of active coenzyme at the site of enzymatic activity. Pyridoxine is thus the preferred prophylactic for UDMH poisoning.

Three groups made up of 20 rats in each group were treated with otherwise fatal doses (130 mg/kg) of UDMH, then treated with a combination of an anti-convulsive (5,5-diphenylhydantoin) and amino acid salts (ornithine- $\alpha$ -glutarate and arginine aspartate) [751, 752]. The mortality decreased to 53%. Other animals treated chronically with lower UDMH concentrations and afforded amino acid therapy avoided the ner-

vous disorder symptoms but not the effects on other organs. This approach is a useful complement to the more popular pyridoxine treatment.

To measure the effect of the combined use of promethazine and naloxone on the survival rate of mice intoxicated by UDMH, 80 male mice were divided randomly into four groups: control group, promethazine group, naloxone group, and combined use of promethazine and naloxone group [753]. For each group, UDMH 15.6 mg/kg was given *i.p.*, and then sodium chloride (0.9%), naloxone (0.12 mg/kg), promethazine (7.5 mg/kg), or naloxone (0.12 mg/kg) combined with promethazine (7.5 mg/kg) was given *i.p.* The symptoms and survival rates of the mice in each group suggested that the combined use of naloxone and promethazine could alleviate the symptoms and significantly postpone the mice dying from UDMH intoxication. Combined use of naloxone and promethazine was more effective in neutralizing the UDMH intoxication than using naloxone or promethazine only.

While a significant number of experimental studies were performed in the late 1950s through the mid-1960s, conflicting information exists concerning the most appropriate treatment for accidental exposures of humans to hydrazines. A cross-sectional study evaluating the most common rocket fuels (e.g., hydrazine, UDMH, MMH, and Aerozine-50) against the most commonly suggested therapies (e.g., pyridoxine, traditional anti-seizure therapies, and arginine) is needed to clarify the treatment implications for human exposure [754]. Treatments that have been useful for hyperammonemic states, such as those for urea cycle defects, have significant potential for the improvement of hydrazine(s) accidental exposure treatment (see also [755]).

The anti-oxidant properties of *salvia miltiorrhiza* have been advertised as a remedy for many ailments. Therefore, it was not surprising to learn that it can even be used as a therapeutic agent to treat UDMH and NTO poisoning. Forty-two rats were divided into three groups: the control group, the inhalation group, and the inhalation plus treatment group [756]. The latter two groups were exposed to 0.98 g UDMH/m<sup>3</sup> for ten minutes and 0.19 g N<sub>2</sub>O<sub>4</sub>/m<sup>3</sup> for ten minutes. After inhalation, the rats in one group were treated with 9 g/kg *Radix salviae miltiorrhizae* extract *i. v.* immediately and 3 g/kg *i.p.* later also. The treatment with *Radix salviae miltiorrhizae* extract appeared to attenuate the consequences of the inhalation of high-concentration UDMH and N<sub>2</sub>O<sub>4</sub>. The anti-oxidant activity of this medicine may be responsible for the protective effect.

In what appears to be a simple *in vitro* test tube experiment, the eliminating effects of vitamin B<sub>6</sub>, vitamin C, and glacial acetic acid on free UDMH were studied [757]. One (1) mg vitamin B<sub>6</sub>, 1 mg vitamin C, or 1 mg glacial acetic acid were added to 10 mL UDMH solution (1 µg/mL), respectively. The free UDMH content was determined after 30 and 60 minutes using the sodium ammino ferrocyanide (TPF) spectrophotometry method at a wavelength of 500 nm. The results revealed that vitamin B<sub>6</sub> can bind 88% UDMH in 30 minutes. Vitamin C or acetic acid had no significant removal effect on UDMH. The chemical mechanism of vitamin B<sub>6</sub> tying up UDMH is that PAM and pyridoxal 5-phosphate monohydrate (PLP) can react with UDMH to form a hydrazone.

The protective effects of curcumin, curcumin-cyclodextrin nano-particle curcumin, and nano-liposomal curcumin on *i.p.* UDMH-induced poisoning in mice were compared in a series of animal tests [758]. Each of the three chemicals reduced several of the many toxic effects of UDMH poisoning to some extent but none provided total protection against UDMH poisoning.

### 1.8.8 Metabolic Fate of UDMH

UDMH metabolizes to at least six different compounds but not all reside in every tissue sample. Based on  $^{14}\text{C}$ -labeled UDMH tests, shortly after the administration of UDMH, one finds 50–60% of the unreacted UDMH, 3–10% of the dimethylhydrazone of glucose, and 20–25% of a yet unidentified higher-molecular-weight compound in urine [433]. The metabolic fate of UDMH was studied in female rats and dogs. The metabolic pathway of UDMH in rats and dogs was studied by *i.p.* injections of  $^{14}\text{C}$ -labeled UDMH and by examining tissue samples after different elapsed times using paper chromatography and autoradiography. The radioisotope tracer technique has been used successfully for  $^{14}\text{C}$ -labeled UDMH [759]. Six radioactive UDMH-derived compounds were found, and three of these were in urine.

The absorption, distribution, and excretion of UDMH in rats, rabbits, cats, dogs, and monkeys were measured using  $^{14}\text{C}$ -tracer and colorimetric methods [760, 761]. UDMH was rapidly absorbed into the blood regardless of the route of administration. It was also quite rapidly excreted by the kidneys, as evidenced by early high concentrations in both blood and urine. UDMH at doses of 20, 40, and 60 mg/kg was rapidly metabolized by rats, as evidenced by the metabolism of UDMH- $^{14}\text{C}$  methyl groups to respiratory  $^{14}\text{CO}_2$  [762].  $^{14}\text{C}$  was also rapidly excreted into the urine after the administration of UDMH- $^{14}\text{C}$  to rats. At low levels of UDMH intoxication, the bulk of the compound was either metabolized to respiratory  $^{14}\text{CO}_2$  or excreted as either UDMH or metabolite(s) in four to six hours after *i.p.* administration of 40 mg/kg of UDMH. UDMH intoxication of rats at doses of 20, 40, and 60 mg/kg appeared to preferentially inhibit glucose catabolism to respiratory  $\text{CO}_2$  via glycolysis and the pentose phosphate pathway. A C-6 decarboxylation process, such as the glucuronate pathway, appeared to be unaffected by UDMH intoxication.

The non-enzymatic formation of methane from UDMH has been reported *in vivo* [763]. The respiratory and urinary excretion of UDMH by rats has been studied using radioactive tracer techniques [764]. Animals given a very low dose of UDMH- $^{14}\text{C}$  metabolized almost 30% of the compound to respiratory  $^{14}\text{CO}_2$  10 h. At a very low dose, almost 30% of the  $^{14}\text{C}$  from *i.p.* administered UDMH appeared as respiratory  $^{14}\text{C}$  in 10 h. At a convulsive dose, conversion of  $^{14}\text{C}$  from UDMH added up to little more than 13% within 20 h. At all doses studied, at least 50% of the radioactivity showed up in the urine (collection period 2 d).

Animals given a very low dose of  $^{14}\text{C}$ -labeled UDMH metabolized almost 30% to respiratory  $^{14}\text{CO}_2$  in 10 h [763]. At the convulsive dose level, 13% was converted to  $^{14}\text{CO}_2$

within 20 h. Rats injected *i. v.* with  $^{14}\text{C}$ -UDMH incorporated only a little radioactivity in liver ribonucleic acid (RNA) [765]. UDMH appears to be a very weak, if not even inactive, methylating agent. The PAM hydrazones of the various hydrazines form as intermediates during the metabolism of hydrazines, surprisingly with exceptionally high toxicity of their own [766]. A comparative study was conducted regarding the toxicity and convulsion activity of UDMH, MMH, and their PAM and pyridoxal-5-phosphate hydrazones. The hydrazones of UDMH were more toxic than UDMH itself when three criteria were compared: **(1)** lag-time before convulsions at various dose levels, **(2)** time of death, or **(3)** LD50. In the case of MMH, the convulsion times of hydrazones and free hydrazine are about equal while death appears earlier with the hydrazones. This work implies that PAM exacerbates rather than alleviates the convulsant activity of UDMH and MMH, and thus should not be considered an antidote. It was discovered that the PAM hydrazone of UDMH is more toxic than UDMH. With MMH and its hydrazone, the convulsion times are equal but death occurred earlier with the hydrazone.

The formation of free radicals as intermediates has been well documented in numerous biological systems, including the metabolism of known toxic drugs. Alkyl hydrazines are particularly susceptible to biological and chemical oxidation processes that lead to the sequential generation of diazene intermediates and carbon-centered free radicals. A study specifically examined the *in vitro* and *in vivo* metabolism of some model alkyl hydrazines to characterize how the nascent radical flux affects metabolite formation and the destruction of cytochrome P-450 [767]. The experimental results demonstrated that all the observed alkyl hydrazine metabolites can be rationalized by assuming the intermediacy of free radicals. The metabolism of the alkyl hydrazines under investigation lead to the loss of hepatic microsomal cytochrome P-450 in a process that was dependent on catalytic turnover. Significant production of free radicals occurs in the metabolism of alkyl hydrazines; these radicals are likely contributors to the toxic sequelae associated with the therapeutic hydrazines and hydrazides used on human patients.

The neutrophil-catalyzed metabolism of hydrazine derivatives to carbon-centered radicals was investigated by a spin-trapping technique [768]. Oxidation of MMH, UDMH, phenylethylhydrazine, or procarbazine by neutrophils led to the formation of alkyl radicals. Azide, an inhibitor of myeloperoxidase, effectively reduced the neutrophil-catalyzed radical yield from the oxidation of MMH but not UDMH. On the other hand, superoxide dismutase and catalase effectively inhibited radical formation in UDMH metabolism by PMA-activated neutrophils, in contrast to MMH metabolism. The results showed that neutrophils can metabolize hydrazine derivatives, with the pathway depending on the hydrazine substitution. Alkyl radical production during the oxidation of mono-substituted derivatives such as MMH was mediated mainly by myeloperoxidase, and that of di-substituted derivatives such as UDMH was mediated mainly by active oxygen species. Similar free radical intermediates were observed during microsomal metabolism of hydrazine.

Metabolites of UDMH in the blood of Wistar rats have been analyzed using SPE followed by HPLC analysis [368]. The blood before UDMH intoxication was collected as a control and analyzed.

#### **1.8.9 Carcinogenic Effects (Carcinogenicity and Carcinogenesis) of UDMH**

Several hydrazines have been shown to be carcinogenic in animal tests. As part of the overall effort to understand the conditions leading to the development of cancer, and to find a cure for this very complex disease, carcinogenic actions of hydrazines have been thoroughly studied. The carcinogenic activity is most pronounced with SDMH and less so with UDMH. Besides hydrazines, UDMH autoxidation products such as dimethylnitrosamine (NDMA) are listed among the most potent carcinogens known. NDMA used to be produced as an intermediate in the manufacturing of UDMH. Throughout the 1960s and 1970s, there may have been traces of residual NDMA in the UDMH that was shipped out of production facilities to the missile silos, but UDMH from the same production lots was also used by toxicity testing laboratories. Because of the increased concern about NDMA carcinogenicity, several UDMH production facilities in the US were shut down since the plants could not be modified to assure zero emissions of NDMA into the surrounding communities. Another plant had to be closed permanently when the demand for UDMH dropped off. For a limited time, in the US, UDMH was prepared using a different process that no longer involved the use of NDMA as an intermediate.

It is not known which process has been used or is currently in use in Russia and the other former countries of the USSR. Shortly after the decommissioning of Russian ICBMs, efforts to sell surplus Russian UDMH in the West have been hampered by concerns about the purity of the product. At that time ARIANE-IV was still using UH-25 as a fuel while France was producing its own UDMH.

The carcinogenic properties of methylhydrazines and NDMA are very similar, such that it was initially suspected that NDMA might be formed as an intermediate during the metabolism of methylhydrazines and might be the real cause for their carcinogenicity. Toxicity warnings about UDMH are often based on data obtained with its much more toxic isomer, SDMH. Traces of SDMH commonly present in UDMH may gravely alter the results of animal toxicity tests, but only a few researchers have verified the absence of SDMH (or NDMA) contamination before starting UDMH exposure tests with animals.

Test animals were administered UDMH by various paths of gavage and were then examined for carcinogenic effects. Summaries on the results of such animal carcinogenicity and DNA alteration tests can be found in [769].

There was a controversy over the adequacy of test methods (lack of concurrent control animals) when carcinogenicity test methods at some animal testing labs were reviewed by federal agencies [594].

1,1-Dimethylhydrazine is a probable human carcinogen that is classified as weight-of-evidence Group B2 under the EPA *Guidelines for Carcinogen Risk Assessment* [770]. Evidence on potential carcinogenicity from animal studies is sufficient, but the evidence from human studies is “No Data.” The potency factor (F) for 1,1-dimethylhydrazine was estimated to be  $82.5 \text{ (mg kg}^{-1} \text{ d}^{-1})^{-1}$  thus placing it in potency group two, according to the EPA Cancer Assessment Group methodology for evaluating potential carcinogens [771]. Combining the weight-of-evidence group and the potency group, 1,1-dimethylhydrazine was assigned a “medium” hazard ranking for the purposes of Reportable Quantity (RQ) adjustment. This potency factor (F) for UDMH,  $82.5 \text{ (mg kg}^{-1} \text{ d}^{-1})^{-1}$ , was an order of magnitude higher than the ( $q_1^*$ ) human carcinogenicity potency factor derived in another EPA study.

#### 1.8.10 Mutagenicity of UDMH

Research on mutagenicity of hydrazines, including MMH and UDMH, complement the work done on carcinogenicity. Not all mutagens are carcinogens and not all carcinogens are mutagens [772]. Because a mutagenicity test can be done quickly *in vitro* in a Petri dish and because it has fewer variables than an animal exposure test, this is usually the first test done when a new chemical is tested for toxicity before it is released to the public. Data from microbial assays with *S. typhimurium* TA98 and a DNA repair test with human embryo lung diploid WI38 suggested that UDMH is metabolically activated *in vitro* by liver microsomes to produce an intermediate that is genetically active. However, UDMH produced negative results in a dominant lethal assay with mice or rats and other animals [773–785]. Unoxidized UDMH was not mutagenic but oxidized samples suspected of containing NDMA were mutagenic [237].

#### 1.8.11 Teratogenicity of UDMH

The embryotoxicity and teratogenicity of MMH, UDMH, and SDMH were investigated with pregnant rats [786, 787]. A dose-dependent reduction in maternal weight gains occurred for all three compounds. A dose-related teratogenic effect did not occur for any of the three compounds. Embryotoxicity, manifested as reduced 20-d fetal weights, occurred only in the UDMH and SDMH high-dose treatment groups. The results indicated that none of the three methylated hydrazine derivatives were selectively embryotoxic or teratogenic in rats.

UDMH may cause disturbances in the structure of synaptonemal complexes in spermatocyte nuclei in mice [788]. Chromosomal abnormalities occurring in the pool of stem cells following a ten-day exposure period were permanently persistent.

### 1.8.12 Bacteriostatic Activity of UDMH

Data on the toxicity of UDMH to bacteria in soil have already been detailed in chapter “Methylhydrazine” in *Encyclopedia of Liquid Fuels*. Readers looking for information about UDMH may find it by reading the MMH chapter.

The toxicities of UDMH and other hydrazines were determined for mixed and unculture cultures of nitrifying bacteria, denitrifying bacteria, and anaerobic methanogenic bacteria [789–791]. MMH was more toxic than hydrazine or UDMH. The toxicity level numbers were small enough to preclude biological waste treatment of these compounds.

During a series of experiments on the death rate kinetics of hydrazine-exposed bacteria cultures, it was noted that bacteria in substrate-free media continued to grow and that metabolites derived from lysed cells were being metabolized. The effects of UDMH, MMH, or hydrazine on the utilization of arbitrarily selected saccharides and compounds involved in the intermediary metabolism were measured as a means of elucidating this mechanism of metabolism [792–795].

The toxicity of UDMH to bacteria may be caused by peroxide intermediates. Seven different recombinant bioluminescent strains of *Escherichia coli* were used to describe the mechanism of toxicity of UDMH on bacteria, as well as to determine whether bacteria can sensitively detect the presence of this compound [238]. It was suggested that the action of UDMH on bacterial cells is caused by hydrogen peroxide, which may be formed in response to the reduction of the air oxygen level.

### 1.8.13 Olfactory Threshold of UDMH

There is a wide discrepancy in reported olfactory threshold values for UDMH and the other hydrazines. Several sources agree that one should not rely on the odor of hydrazines as a warning for imminent acute or sub-acute exposure because it may cause olfactory fatigue. Also, the olfactory threshold is far above the established safe levels. A comparison table in the chapter titled “Methylhydrazine” summarizes the reported olfactory threshold of hydrazines in comparison to former and current American Conference of Governmental and Industrial Hygienists (ACGIH®) threshold limit values.

Methylhydrazines have a more distinct fishy odor than hydrazine, although it would be difficult to differentiate them from methylamine or DMA, which are common constituents of fish degradation products. A group of volunteers was exposed to UDMH vapors at concentrations of 0.2, 0.3, or 0.5 ppm [796]. The odor threshold level for UDMH has been generally quoted at 6 to 14 ppm for UDMH. The value for UDMH olfactory threshold is 12 to 28 times the threshold limit value. Seven years of field experience by personnel have indicated that the actual odor thresholds are considerably below these values. Since odor threshold levels are used by safety and operating personnel at Cape Kennedy as an indication of exposure, it was considered appropriate to evaluate this field experience. Based on these data and the results of some controlled studies, it was concluded that the actual odor

thresholds are less than 0.3 ppm for UDMH. The test objects described the odor as “fishy, unpleasant, restroom-like, ammonia-like, rotten-fish type, etc.” Back in 1959, before much was known about UDMH toxicity, one of the studies [797] suggested that “*The odor threshold of the vapor appears to offer an adequate warning of the presence of hazardous concentrations.*” Notably, this attitude has changed considerably in the 60 years since.

#### 1.8.14 Epidemiological Studies of UDMH Exposures

While epidemiological studies of workers exposed to hydrazine  $\text{N}_2\text{H}_4$  or hydrazine hydrate in the workplace have been published, no comparable studies exist for UDMH. It is difficult to estimate the number of workers exposed to UDMH over the past 60 years because UDMH was used (and is still being used) at so many different locations around the world.

The *National Occupational Exposure Survey* (1981–1983) estimated that 2917 workers were potentially exposed to UDMH [798]. This estimate was based only on observations of the actual use of the compound. The *Toxic Chemical Release Inventory* (EPA TRI) listed four industrial facilities that produced, processed, or otherwise used UDMH in 1988 [799]. In compliance with the Community Right-to-Know program in the US, the facilities reported releases of UDMH to the environment that were estimated to total 4300 lb. TRIs have been compiled every year since 1988. The reports have become more detailed and the databases more readily accessible to the public as the years have gone by. The 1979 Toxic Substances Control Act (TSCA) Inventory identified four companies that together produced 55000 lb of UDMH in 1977 [800].

Air sampling during fuel transfer operations was once done in conjunction with the evaluation of respiratory protection (gas mask canisters) for workers at Rocky Mountain Arsenal. Measurements were of the order of 2 ppm hydrazine and 3 ppm, or even up to 4.6 ppm UDMH. Air samples were taken in 1976 and 1977 during drum and truck/rail tanker filling operations [801]. The sampling methods used were sulfuric acid-coated silica gel tubes and impingers. Air samples were taken both outside and inside gas masks worn by propellant handlers. Outside air samples were typically of the order of 0.2 ppm for hydrazine and UDMH, with peak excursions of 1.66 ppm hydrazine or 1.98 ppm UDMH. The air inside the gas masks was clean. If there was any hydrazine or UDMH, it was close to the detection limit. The TLV in effect at the time was 1 ppm for hydrazine and 0.5 ppm for UDMH but lowering of the TLVs to 0.1 ppm was imminent. The odor of hydrazine and UDMH was noted when walking past the storage area, which was outside the general work area. NDMA was detected in the air in the vicinity of UDMH storage tanks. Some of the operating procedures had been improved and necessary repairs were made before the inspection team returned several months later. Shortly before the facility was shut down, air samples were taken and analyzed for NDMA in 1980 while railroad cars and tankers were cleaned and loaded [802]. NDMA was found in the entire area, using two different sor-

bent tube materials. Since there was no gas mask with proven effectiveness against NDMA, industrial hygiene staff recommended that compressed air respirators should be worn when working in the area. Another inspection two years later, after the operations were shut down, found no detectable hydrazine or UDMH in the air (D.L. of  $0.05 \mu\text{g}/\text{m}^3$   $\text{N}_2\text{H}_4$  or  $0.1 \mu\text{g}/\text{m}^3$  UDMH) but found persistent NDMA levels of typically  $2 \mu\text{g}/\text{m}^3$  (D.L.  $0.05 \mu\text{g}/\text{m}^3$ ) with excursions of  $20 \mu\text{g}/\text{m}^3$  [803]. The silica sorbent for hydrazine(s) analysis was replaced with fire brick for the later set of analyses.

It was reported that personnel exposed to UDMH suffered from aprosexia, hypomnesia, and hepatitis with increasing work duration [685]. Based on a review and risk analysis of the toxicity, toxic mechanism, and poisoning symptoms of UDMH, it was suggested that health care, nutrition care, and stricter environment inspections are effective protection measures.

Throughout the many years that ARIANE-1 through ARIANE-4 was in service as a satellite launcher, the ground personnel at the Kourou launch site observed all safety regulations. There were no serious poisoning incidents at the time because adequate safety precautions were always taken [804].

### 1.8.15 History of UDMH Accidents

Two workers who had inhaled UDMH vapor at a distance of 700 m from the source of the fumes experienced initial choking. Four hours later, both men became extremely nauseated and both vomited. Both reported the taste of UDMH being left in the mouth [717]. At the arsenal, careful pre-employment analysis of men was carried out, including cephalin flocculation and thymol turbidity tests. The observations were repeated every two weeks. Only a sub-clinical toxic state was noted in five individuals. After six months, no clinical evidence of toxicity was observed but positive cephalin flocculation was noted. Comparable results were found in another group of six men. Findings indicated that UDMH may produce pulmonary irritation, delayed gastro-intestinal irritation, haemolysis, and convulsions in humans. In another group of tank farm workers who transferred UDMH from tank cars into 55-gal drums, several individuals had abnormal RBCs, WBCs, and cephalin flocculation.

A propellant technician performing transfer of UDMH from a tanker to another container was involved first in a spill, followed by an explosion and fire with ignition of the patient's clothes, leading to them suffering severe burns (53% of upper body surface) and UDMH poisoning [805]. The patient appeared to have stabilized 40 h post-accident but complications (a drop of systolic blood pressure from 120 to 60 mm Hg) developed during anesthesia in preparation for planned surgery and skin grafting. The surgical procedure had to be abandoned. Proper antidote information was not obtained until 48 h after admission. The team then proceeded with injections of 25 mg/kg pyridoxine (25% *i.v.*, 75% *i.m.*) and ornithine ketoglutarate (35 g/24 h continuously *i.v.*). Improvement occurred within minutes of this treatment. The pyridox-

ine dose was repeated twice during the two following days. Finally, after 5 d, the patient was stabilized enough to undergo surgery for his burn wounds.

On 1 February 1988, in a railway cargo train near the city of Yaroslavl in Russia, three tank cars containing UDMH left the tracks, and approximately 740 L was spilled from one overturned tank [565]. The volume of soil that was strongly polluted (up to 20 g UDMH/kg of soil) was 150 m<sup>3</sup>. More than 1100 persons, many inadequately prepared to deal with the hazards of this chemical, participated in the clean-up effort associated with the train accident. Out of the group of 1100 participants, 58 were seriously poisoned and required hospitalization (see also [806]).

### 1.8.16 Toxicity of NTO/UDMH Reaction Products

Most of the UDMH toxicity publications deal with exposure to only the fuel vapors. In real life, however, in the case of leakage of storable propellants at a launch site (a leak not severe enough to cause instant ignition), the personnel responding to an emergency may be exposed to mixtures of UDMH and NO<sub>2</sub> vapors. This situation was simulated in a series of animal tests.

It is already extremely hazardous if living beings are exposed to UDMH by itself or NO<sub>2</sub> by itself, but the combination of the two poisons, as it may be encountered after launch vehicle failures, may aggravate the situation. The oxidative damage parameters of mice poisoned by inhaling gas mixtures containing NO<sub>2</sub> (N<sub>2</sub>O<sub>4</sub>) and UDMH were studied by randomly dividing a group of 40 mice into a control group and three experimental exposed groups [807, 808]. The mice of the three experimental groups were put into an exposure cabinet 2 h/d for four successive days. The concentrations of the mixed propellants in the cabinet were 10, 90, and 400 mg/m<sup>3</sup>, respectively. The mice were weighed and killed on the fifth day, and the content of malondialdehyde (MDA) and the activity of Total Superoxide Dismutase (T-SOD) in serum and lung tissue and content of lipofuscin in liver homogenate were measured. The weight of the mice in the 400 mg/m<sup>3</sup> group was significantly lower than that of control group (P 0.01). The serum MDA content of the 400 mg/m<sup>3</sup> group was significantly lower than that of control group (P 0.05). The lung tissue MDA contents of all three experimental groups were significantly lower than that of control group (P 0.01). The plasma T SOD activity of the animals in the 90 mg/m<sup>3</sup> group was significantly lowered (P 0.01). The T SOD activity of lung tissue in the 10 and 90 mg/m<sup>3</sup> groups was significantly lowered. Despite these changes, the variations of the oxidative damage parameters showed that there was no significant lipid peroxidation damage in the poisoned mice.

In another study of combined injury caused by blast and liquid propellant poisoning, 392 male Wistar rats were divided randomly into seven groups: blast injury group, UDMH group, N<sub>2</sub>O<sub>4</sub> intoxication group, blast injury accompanied with intoxication of UDMH group, blast injury accompanied with intoxication of N<sub>2</sub>O<sub>4</sub> group, blast injury accompanied with intoxication by UDMH and N<sub>2</sub>O<sub>4</sub> group, and a normal control group [809]. The excess pressure of the blast wave was 471 kPa and the pos-

itive pressure was sustained for 55–60 ms. To establish the blast-toxicosis combined injury model, rats were exposed to UDMH 800 ppm or/and  $\text{N}_2\text{O}_4$  43 ppm through inhalation in an intoxication tank for 15 minutes immediately after the blast injury. The clinical conditions of experimental rats were observed, and the animals were killed sequentially 3, 6, 12, 24, 48, and 72 h after injury for blood gas analysis and biochemical examination. According to the clinical observations and the results of blood gas analysis and biochemical examinations, a blast-toxicosis combined injury model was established successfully. Injury caused by the explosion of liquid hypergolic propellants can be simulated by combining the blast wave tube and the intoxication tank. The establishment of the model should be of great significance for the interpretation of actual accidents that have happened.

In a similar experiment, test animals (rats) were exposed to simulated launch mishap vapors under controlled conditions [810, 811]. Rats were exposed to combination blast effects and poison injury with  $\text{N}_2\text{O}_4$  and UDMH to study the effect of blast-poison combined injury on the blood gas analysis and pathomorphological changes. A total of 168 healthy male rats were exposed to blast waves at 471 kPa. After ten minutes of blast injury, the rats were randomly divided into three groups. The rats continuously inhaling UDMH were labeled as the BU group, the rats inhaling  $\text{N}_2\text{O}_4$  were the BN group, and the rats inhaling both UDMH and  $\text{N}_2\text{O}_4$  were the BUN group. The clinical symptoms of the rats in the BUN group were aggravated progressively, the pulmonary alveoli were diffusely filled with pink exudate and large patchy hemorrhage, and pneumorrhagia and pneumonedema were aggravated. Cloudy swelling or hyaline degeneration occurred in the cardiac muscle cells in different degrees and individual myocardial fiber was broken. The myocardial mesenchyme was loose, and hemorrhage and edema occurred. The pathologic change of the myocardium was aggravated. Dilation of the hepatic sinusoid and cloudy swelling in the hepatic cells were observed. The partial pressure of oxygen in the artery ( $P_a\text{O}_2$ ) in all three groups significantly decreased at 3–12 h after injury and reached the lowest point at 3–6 h after injury. The decreasing period of the  $P_a\text{O}_2$  in the BUN group lasted longest and it recovered more slowly than that of the other two groups. All the animals had more serious symptoms in the respiratory system with the combined exposure to blast injury and poisoning by  $\text{N}_2\text{O}_4$  and UDMH. The animals in all the three groups had pathomorphologic changes and they were the worst in the BUN group.

### 1.8.17 Maximum Allowable Exposure Levels of UDMH

The considerations in establishing maximum allowable exposure limits for hydrazines in general and UDMH in particular have already been discussed in an earlier section in this chapter while exploring the maximum allowable exposure levels of MMH.

The Committee on Toxicology of the National Research Council (NRC) published *Guides for Short-Term Exposure of the Public to Air Pollutants*, which included UDMH,

MMH, and hydrazine [812, 813]. The short-term public exposure limit (STPL) and short-term exposure limit (STEL) limits recommended by that committee are compared in Table 18 and in a similar table in the chapter on MMH.

**Table 18:** Olfactory thresholds and exposure limits for UDMH.

| Type of data <sup>a</sup> | UDMH concentration, ppm by volume | References |
|---------------------------|-----------------------------------|------------|
| Olfactory threshold       | 0.5–1.0                           | [796]      |
| Olfactory threshold       | 6–14                              | [708]      |
| ACGIH-TLV (1981)          | 0.5 (skin)                        | [814]      |
| ACGIH-STEL (1981)         | 1                                 |            |
| ACGIH-TLV (1998)          | 0.01 (skin) A3                    |            |
| NRC-EEL, 10 min           | 100                               | [815]      |
| EEL, 10 min               | 200                               | [816, 817] |
| NRC-EEL, 30 min           | 50                                | [815]      |
| EEL, 30 min               | 100                               | [816, 817] |
| NRC-EEL, 60 min           | 30                                | [815]      |
| EEL, 60 min               | 50                                | [816, 817] |
| NRC-STPL, 10 min          | 50                                | [812, 813] |
| NRC-STPL, 30 min          | 25                                |            |
| NRC-STPL, 60 min          | 15                                |            |
| NRC-PEL*, 10 min          | 100                               |            |
| NRC-PEL, 20 min           | 50                                |            |
| NRC-PEL, 30 min           | 30                                |            |

EEL = Emergency exposure limit, STEL = Short-term exposure limit, PEL = Public emergency limit

The standard operating procedure for the establishment of Acute Exposure Guideline Levels (AEGLs) is described in [818]. They list the publications that were considered in setting these limits. AEGLs are established for the general population, not just for healthy working populations covered by the TLV-TWA. AEGL-1, AEGL-2, and AEGL-3 values for UDMH are listed in Table 19.

**Table 19:** AEGL limits for UDMH.

| AEGL level             | 10 min. | 30 min.                            | 1 h                               | 4 h                                 | 8 h                                 |
|------------------------|---------|------------------------------------|-----------------------------------|-------------------------------------|-------------------------------------|
| AEGL-1 (non-disabling) | NR      | NR                                 | NR                                | NR                                  | NR                                  |
| AEGL-2 (disabling)     | 18 ppm  | 6 ppm<br>(14.7 mg/m <sup>3</sup> ) | 3 ppm<br>(7.4 mg/m <sup>3</sup> ) | 0.75 ppm<br>(2 mg/m <sup>3</sup> )  | 0.38 ppm<br>(1 mg/m <sup>3</sup> )  |
| AEGL-3 (lethal)        | 65 ppm  | 22 ppm<br>(54 mg/m <sup>3</sup> )  | 11 ppm<br>(27 mg/m <sup>3</sup> ) | 2.7 ppm<br>(6.6 mg/m <sup>3</sup> ) | 1.4 ppm<br>(3.4 mg/m <sup>3</sup> ) |

NR = not recommended

Data source: [819]

Numeric values for AEGL-1 were not recommended because of several reasons: **(1)** the lack of available data, **(2)** the data indicated that toxic effects may occur at or below the odor threshold, **(3)** the inadequate margin of safety that exists between the derived AEGL-1 and the AEGL-2, or **(4)** the derived AEGL-1 is greater than the AEGL-2. The absence of an AEGL-1 does not imply that exposure below the AEGL-2 is without adverse effects. The NRC AEGL committee treated both dimethylhydrazines together, although they acknowledged that 1,1-dimethylhydrazine may be somewhat more toxic than SDMH [820]. In a 2001 re-evaluation of AEGL data for UDMH, the ten-minute AEGL-2 level was set at 18 ppm and the ten-minute AEGL-3 level was set at 65 ppm [821]. The original (SCP) *Immediately Dangerous to Life and Health* (IDLH) concentrations of 50 ppm for UDMH were later revised to 15 ppm [822, 823] (see also [815, 824, 825]).

### 1.9 Environmental Impacts of UDMH

The US EPA has issued several *Health and Environmental Effects Profiles* for hydrazines that contain sections on environmental effects in addition to toxicity information [707]. There is substantial concern about the environmental fate of residual UDMH and NTO from the Russian launch vehicles that crash in remote corners of Kazakhstan. The descent of the first stages of Proton launch vehicles is accompanied by the spill of unburned UDMH and NTO in amounts ranging from 0.6 to 4 tons, of which 10–30 kg reach the ground and are subsequently spread over the surface.

Attempts have been made to model the spread of this contamination in the environment and to explore possible paths of degradation and adsorption to soil [781, 826, 827]. Several UDMH degradation compounds were predicted to exhibit high probabilities for potential carcinogenicity, mutagenicity, teratogenicity, and/or embryotoxicity. The compounds were ranked based on their predicted human health impact using partial order ranking methodologies that highlight which compounds on a cumulative basis should receive major attention, i.e., NDMA, 1,1,4,4-tetramethyltetrazene, trimethylhydrazine, acetaldehyde dimethylhydrazone, 1,1-formyl-2,2-dimethylhydrazine, and FDMH, respectively.

Many of the earlier publications expressing concern about the pollution of spent stage impact areas in Kazakhstan were based on assumptions and computer models. As of 2018, there is only one solid study that is based on actual field observations at the impact sites. The most comprehensive and detailed account of the environmental impact of spent launch vehicles in the first and second stages in Kazakhstan was published in 2018 [828]. During the early years of the operation of the launch vehicle model PROTON-K, residual propellants remained in the first stage after its separation from the upper stage. In most cases, it led to an explosion after hitting the ground. In the case of the more recent, improved design Proton-M, most of the first stage residual

propellants were ejected from the tanks after stage separation through a drain valve and, therefore, did not reach the ground.

The number of PROTON launches ranged from three to 11 times a year in the period 2010–2016. The leakage of UDMH from a single-stage impact incident covered an area up to 737 m<sup>2</sup>. UDMH was detected mainly in the snow of the PROTON first stage falling sites where its concentration reached up to 2200 mg/L (the most common range of concentrations was 0.1–0.2 mg/L). In sporadic soil samples, it was up to 1.5 mg/kg. UDMH was detected mainly in winter. In early spring the content of UDMH was 0.09–0.69 mg/kg in the soil, while in summer it did not exceed 0.05 mg/kg. In the N<sub>2</sub>O<sub>4</sub> leakage areas, the content of NO<sub>3</sub><sup>−</sup> increased up to 22.3 g/L in the snow and 24.8 g/kg in the soil. In the places where UDMH leakage had occurred, pH values in the snow and soil increased to 10.3 and 9.4, respectively and the background values varied from 5.1 to 7.9 and from 6.6 to 8.3, respectively. UDMH contamination occurred in only 50% of collected samples at a distance no further than five meters from the metal fragments of the stage. NDMA was detected in both snow and soil. Maximum values reached 239.9 mg/L in snow, and the most common concentrations were in the range of 0.2–0.4 mg/L. NDMA was found in only 11% of soil samples and in 46% of snow samples collected no further than 5 m from the fragments of the stage. The maximum NDMA concentration reached 13.9 mg/kg. The operation of heavy vehicles in soft soils during the recovery of fragments of the launch vehicle first stage for scrap metals recycling can expand the contaminated zone and add to the environmental damage. The Proton second stages contain less propellant and experience more aerodynamic heating during re-entry. In the impact sites of the Proton second stages, the main adverse effect was associated with the mechanical pollution of eco-systems with the fragments of fallen stages. They did not detect chemical pollution in the soil and snow surrounding second-stage fragments during three years of observation (see also [552]).

It appears that the heat from aerodynamic braking of second-stages re-entering the atmosphere at a much higher speed than the first stages causes most of the residual propellants to evaporate and disperse along the ballistic re-entry path. There are computer programs for calculating the chance of orbital debris hitting the ground (*Object Reentry Survivability Analysis Tool* and *Spacecraft Atmospheric Reentry and Aerothermal Breakup*) but they are rarely applied to the second stages of launch vehicles [829]. The launch vehicle second stages are separate from the third stages at a height of 130–160 km. Owing to aerodynamic overloads at a height of 30–50 km, the stages are destroyed and most of the second stage fragments burn out, leaving the remaining fragments to fall to the ground, scattering considerably within a range of falling sites. Residual propellants burn out and metals start melting due to the thermal heating, or they disperse in the atmosphere before reaching the Earth's surface. No more than 5% by weight of the second stages reached the ground [830].

### 1.9.1 Aquatic Toxicity of UDMH

Several data on the aquatic toxicity of UDMH on fish, algae, invertebrates, amphibians, and crustaceans in water have already been discussed in sections on the same topics when considering MMH previously. Therefore, readers looking for UDMH information may find it by scanning through these sections. The aquatic toxicity of UDMH to algae, bacteria, invertebrates, amphibians, crustaceans, and fish have already been described in detail in [831] (see also [290, 291, 832–836]).

### 1.9.2 Degradation of UDMH in the Environment

Howard's *Handbook of Environmental Degradation Rates* [837] provides data for a large number of chemicals, including UDMH, SDMH, MMH, hydrazine, and NDMA. The environmental chemistry of hydrazines continues to receive interest [838]. One of the many degradation products of UDMH is 1-formyl-2,2-dimethylhydrazine,  $(\text{H}_3\text{C})_2\text{N}-\text{NH}-\text{CHO}$ , CAS RN [3298-49-5], which was found in UDMH-contaminated water and soil samples. Under certain conditions (alkaline hydrolysis), it can hydrolyze and release UDMH back to the environment [380]. This is very similar to FDMH,  $(\text{H}_3\text{C})_2\text{NN}=\text{CH}_2$ , CAS RN [2035-89-4]. A detailed study of the environmental fate of UDMH and its by-product NDMA provided a summary of published literature on the degradation of UDMH in water, soil, and the air, and the types of follow-on products formed during this process [839].

#### 1.9.2.1 Degradation of UDMH in Water

The rate of UDMH degradation in water depends on the degree of oxygen saturation, temperature, and hardness of the water. Sunlight and dissolved transition metal salts will accelerate the process. The rate of autoxidation of UDMH in distilled water with a carefully controlled degree of oxygen saturation was already discussed in an earlier section of this chapter. Similar studies were performed for hydrazine and MMH.

Hard and soft water samples, with and without the addition of UDMH, were examined over a 96-h period for changes in alkalinity (with two different pH indicators), pH, specific conductance, ethylenediamine tetraacetic acid (EDTA) hardness, and D.O. [840]. The D.O. content changed more rapidly in hard water than in soft water.

Decomposition (degradation and autoxidation) of UDMH proceeded more rapidly in pond water than in seawater [841, 842]. After 10 d, 40% had decomposed in pond water and 30% in seawater. No change could be detected in distilled water. Half-life times of UDMH and other hydrazines have already been detailed Table 13.

Under open-air conditions, the rate of degradation of UDMH in surface water is fast, with no sharp increment of the contents of degradation products such as formaldehyde or cyano group ( $\text{CN}^-$ ) [843]. The UDMH degradation is influenced by many factors such as the hydrological conditions, daylight illumination, temperature, and acidity.

One of the autoxidation products of UDMH in water, air, or soil is NDMA. In water, it was noticed that NDMA is easily evaporated and photolyzed in aqueous solutions. The rate of evaporation is higher at alkaline pH but the rate of photolysis is greater in acidic solutions. Evaporation only converts a water pollution problem to an air pollution problem. If there is concern about the evaporation from a caustic UDMH-NDMA waste stream, it should be neutralized and acidified to enhance photolysis over evaporation.

Vacuum-assisted headspace SPME (Vac-HSSPME) followed by GC-MS was used for the quantitative analysis of UDMH transformation products in surface water samples [844]. The target transformation products were pyrazine, 1-methyl-1*H*-pyrazole, NDMA, *N,N*-dimethylformamide, 1-methyl-1-1,2,4-triazole, 1-methyl-imidazole, and 1*H*-pyrazole. For these analytes, and using shorter sampling times, Vac-HSSPME yielded detection limits (0.5–100 ng/L) that were three to ten times lower than those reported for regular HSSPME. Vac-HSSPME sampling for 30 minutes at 323 K (50 °C) yielded the best combination of analyte responses and their standard deviations (<15%). 1-Formyl-2,2-dimethylhydrazine and formamide were discarded because of poor precision and accuracy when using Vac-HSSPME. The recoveries for the rest of the analytes ranged between 80 and 119%.

### 1.9.2.2 Degradation of UDMH in Air

The rate of UDMH degradation in ambient air depends on the intensity of sunlight, relative humidity, and the presence of other air contaminants like ozone and nitrogen dioxide. The rate of autoxidation of UDMH in dry air in carefully controlled atmospheres in laboratory atmospheric research chambers has already been discussed in section “Autoxidation of UDMH in Air” above. Similar tests were conducted with hydrazine and MMH vapors.

The rate of evaporation of UDMH and the other two propellant hydrazines from a Petri dish in air was already detailed in the chapter on methylhydrazine. As stated, there is a gradual increase in the rate of evaporation and a half-life time in air or water going from hydrazine to MMH and going from MMH to UDMH.

The autoxidation of UDMH and a 50:50 mixture of UDMH and hydrazine (Ae-50 blend) was studied in a 300-mL Pyrex flask, at a partial pressure of 5 mmHg in a 44-cm path length IR spectrophotometer cell, and in a long path 55-L reaction cell constructed of a 0.152-m × 3.05-m section of Pyrex pipe [228]. With initial UDMH partial pressures of several mmHg, autoxidation proceeded too slowly to be differentiated from natural decay processes. When the initial UDMH pressure was lowered to a few ppm, the addition of oxygen caused an approximately first-order decay with a half-life of about 84 h. The main oxidation product under these conditions was FDMH. The 50-50 blend did not behave as two independent systems. Instead, there were substantial positive synergistic effects observed. At concentrations of a few mmHg of each component, the addition of oxygen resulted in a 10- to 20-fold increase

in decay rate over that shown by UDMH or hydrazine by itself. At ppm concentration levels, the situation was similar for UDMH, where a four-fold oxidation rate increase was observed when compared with a similar experiment with no hydrazine present. However, hydrazine oxidation in the 50-50 blend was somewhat slower than it was in a similar experiment with only hydrazine present.

Previous air pollution studies assumed that UDMH dumped from launch vehicles prior to re-entry was very diluted and totally evaporated as a vapor, especially at low pressures in a high atmosphere. But what happens if large quantities of liquid UDMH are suddenly released in the high atmosphere as the result of unburnt fuel re-entering with an upper stage or stage fragmentation as the result of a launch disaster? Will UDMH attach itself to water/ice in the clouds and then snow or rain onto the surroundings? In trying to find an answer to such questions, it has been attempted to model the behavior of UDMH aerosol droplets in the atmosphere [549, 845–847].

The evaporation of NTO or UDMH in ambient air after residual propellants were dumped overboard from upper stages is fast enough that droplets most likely will not reach the ground [544, 848, 849].

If the sudden atmospheric release of UDMH (Ae-50) is the result of a launch disaster of a TITAN-II, -III, or -IV launch vehicle, the toxic cloud will initially consist of a mixture of unreacted fuel and oxidizer vapor at non-hypergolic and below-flammable concentrations. The dispersion of such propellant clouds has been modeled using an atmospheric dispersion computer program [850]. The gas-phase reaction of UDMH with  $\text{NO}_2$  in the cloud of exploded propellants leads to the formation of tetramethyltetrazene-2 and NDMA [271].

Reactions of UDMH with selected species of interest that are found in the environment have been investigated [851]. Included were aqueous-phase reactions that can occur in atmospheric aerosols, raindrops, groundwater, or soils in contact with groundwater, as well as selected gas-phase reactions. Reactants include oxygen and hydrogen peroxide (both reactants in the presence and absence of catalysts), ozone, nitrous acid, sulfur dioxide, and acetone (as a model for environmental ketones and aldehydes). Rate constants for the reactions have been determined, or upper limits set. In several instances, reaction products have been identified. By far the fastest reactions measured were those involving the hydrazines and ozone with (second-order) rate constants up to  $2.4 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1}$ .

The first and second stages of Russian expendable launch vehicles re-entering the atmosphere are said to scatter large amounts of unburnt propellants during re-entry and impact on the ground. So far, most of the interest was directed at UDMH that survived the impact, and most investigators ignored the simultaneous presence of NTO at the impact site. Because the fuel tanks are attached to the outside of the core oxidizer tank on the Proton vehicle, they may separate during re-entry and impact at different locations. Some of the NTO must be reacting with the UDMH if both are released at the same time at the same impact location. Several of the impacts have resulted in fires.

Rockets such as PROTON or DNEPR using UDMH and NTO propellants accounted for about one-third of all stratospheric rocket engine emissions, which was comparable to solid-fueled rocket emissions. Plume and global atmosphere models were developed to estimate local and global ozone depletion caused by NO and H<sub>2</sub>O emissions from the PROTON rocket, which is the largest UDMH-fueled launcher in use [852]. NO and H<sub>2</sub>O emission indices were assumed to be 20 and 350 g/kg (propellant), respectively. Predicted maximum ozone loss in the plume of a PROTON rocket would be 21% at 44 km altitude. Plume ozone loss at 20 km equals 8% just after launch. Predicted steady-state global ozone loss from ten PROTON launches annually is  $1.2 \times 10^{-4}\%$ , with nearly all the loss being due to the NO component of the emission. Normalized by stratospheric propellant consumption, the global ozone depletion efficiency of the PROTON is approximately 66–90 times less than that of solid-fueled rockets. From 2019, the PROTON was gradually phased out from service. Therefore, this problem should go away with time, although China and North Korea, and some Indian launch vehicles continue to use NTO and UDMH or NTO and UDMH fuel blends like UH-25.

### 1.9.2.3 Degradation of UDMH in Soil

Studying the degradation of alkylhydrazines in soil is a dual project. Firstly, the disappearance of hydrazines as they are digested by bacteria is measured. Secondly, the toxic effects of hydrazines that might kill the bacteria or induce irreversible mutations are measured. The fatal toxicity of alkylhydrazines to bacteria was previously detailed. Therefore, the first topic only is discussed here.

Degradation of UDMH and other hydrazines in the soil takes place via several mechanisms. The most active mechanism for the degradation and destruction of UDMH in soil is biodegradation, where UDMH and its decomposition products serve as nutrients for certain types of bacteria. In sterile soils, in the absence of bacteria, autoxidation would be the main degradation mechanism if air can freely diffuse through the soil. In wet climates, oxygen-saturated rain will carry in more oxygen and wash out and dilute the UDMH. Some of the UDMH may be firmly adsorbed to high surface area clays. Some of the UDMH may react with aldehyde and carbonyl groups in carbohydrates that are naturally present in humus-rich soil and become immobilized until its host molecule becomes consumed by another slow process. In aerated soils, the spilled UDMH will autoxidize and form NDMA. NDMA is more persistent and degrades in the soil much more slowly than UDMH [853, 854].

Both UDMH and hydrazine are strongly adsorbed or decomposed on clay particles. Montmorillonite and kaolinite clays, as well as test soils, seem to accelerate the decomposition of the UDMH and hydrazine [834].

Undiluted hydrazine, UDMH, and Aerozine-50 moved through a 50-cm (20-in.) soil column when leached with 22.8 cm (9 in.) of water [855]. Toxic concentrations of the test chemicals, as measured by the growth of rice, remained in the 30- to 50-cm (12- to 20-in.) depths after 22.8 cm (9 in.) of water had been leached through the columns.

Adsorption isotherms of UDMH vapor on peat soil were measured between 305 and 323 K using a dynamic method [856]. The differential enthalpy of adsorption was calculated from the temperature dependence of adsorption. One of the potential methods for the clean-up of UDMH-contaminated soil was thermal treatment. The desorption isotherms of UDMH from soil need to be known to optimize this process and determine how long it will take to effectively remove all UDMH contamination from soil by baking it.

Soil percolation/adsorption tests were conducted with UDMH (0.1% solutions) using four different types of soils (sand, clay, organic, and one typical for Vandenberg AFB) [248, 249]. The soil samples were mostly sandy soils with little cation exchange capacity. All soils were dried at 353 K for 24 h, which should have killed most of the soil bacteria. Yellow-colored autoxidation products interfered with colorimetric determination. GC/MS was a more reliable method in the presence of autoxidation products. Table 58 in *Encyclopedia of Liquid Fuels* in the chapter "Methylhydrazine" summarized the adsorption/extraction results obtained after soaking 3-g soil samples for 20 minutes with 30 mL of 0.002 vol.-% solutions. No fuel interaction was observed with clean sand (as in the percolation studies) but strong effects were observed in all natural soil samples. The strongest interaction was with clay-type soils. Hydrazine and MMH were more reactive than UDMH in all soils. In soil percolation tests, fuel solutions were applied to a 200-g soil sample in a column and leached with 500 mL of water. In the case of UDMH, 100% of it was leached from sand with the first 50 mL. However, in humus, a strong interaction was observed and less than 20% could be recovered after extraction with 500 mL of water.

As soon as UDMH enters the soil, some of it vaporizes, and the elevated moisture of the soil promotes an increase in the UDMH concentration at the initial moment. Then, the concentration levels off toward the end of observation. It was found that the higher the organic matter content in the soil, the higher the remaining UDMH concentration. However, at the end of the observations, on the 90<sup>th</sup> day, the total UDMH concentration did not exceed 0.5% of its initial content. To explain the UDMH behavior in soils, one must take into account the existence of different forms of this substance and the changes in their ratios with time. The main portion of UDMH retained by the soil in the free form is transformed during the first few days. HPLC and MS were used to identify the decomposition products of UDMH in soils [857–859]. Decomposition products of UDMH included DMA, FDMH, methylhydrazine, trimethylhydrazine, NDMA, 1-methyl-1,2,4-triazole, formic acid dimethylhydrazide, 1,5,5-trimethylformazane, 1-methyl-1,6-dihydro-1,2,4,5-tetrazine, *N,N*-dimethylaminoguanidine, and several other products. High-reliability structure identification was achieved using independent methods, including gas chromatography-mass spectrometry, <sup>1</sup>H and <sup>13</sup>C NMR, and UV spectroscopy, and by measuring retention times and spectral characteristics after the synthesis of the suggested structures by other methods. Some intermediate products of the decomposition of

UDMH that are potentially capable of temporarily bonding and later releasing UDMH were characterized. Some less polar intermediates had high migration mobility in soils.

Procedures were developed based on liquid chromatography/MS for determining the transformation products of UDMH in soils, including formic acid dimethylhydrazide (identical with 1-formyl-2,2-dimethylhydrazine), 1-methyl-1,2,4-triazole, 1,1-dimethylguanidine, and DMA [369]. For sample pre-treatment, the use of extraction with methanol (for 1-formyl-2,2-dimethylhydrazine) and ultrasonic extraction with a weakly alkaline buffer solution (for other substances) was used.

One of the most stable transformation products of UDMH is MTA, which was analyzed in contaminated soils using SPME in combination with gas chromatography-MS. Quantitation of organic compounds in soil samples using SPME is complicated by a matrix effect. Thus, an isotope dilution method was chosen using deuterated analyte (1-(trideuteromethyl)-1*H*-1,2,4-triazole) for matrix effect control [460, 860] (see also [861–864]).

The effect of different soil-geochemical factors on the migration of UDMH in the landscape and the effect of organic matter, acid-base properties, particle size distribution, and mineralogy on the decrease in the concentration of UDMH in equilibrium solutions has been studied [865].

Snow cover contamination was measured in the impact areas of the first stages of the PROTON launch system in central Kazakhstan [866, 867]. It was found that the chemical effect of propellants on the snow cover is local. The increase in the content of the following toxic substances in the snow was registered: UDMH, NDMA, nitrate, and nitrite ions. Most of the pollutants were localized in the upper 5-cm snow layer. Dinitrogen tetroxide decreased the value of pH while UDMH increased it. The in-flow of calcareous soil particles from dust storms and their subsequent fallout result in the alkalization of snow and in the neutralization of acidification by dinitrogen tetroxide accompanied by the formation of the salts of nitric acid and nitrous acid (see also [552]).

UDMH behavior in soils depends on the properties of the soils, concentrations of the pollutant, and the soil's mineralogical composition. In wet soils, the UDMH concentration at the initial moment was higher than in the dry soils. However, subsequently, differences level out, and at the end of the 90-d observation, UDMH concentrations did not exceed 0.5% of the initial load regardless of the humidity. If the load of UDMH was 4 kg/m<sup>2</sup>, 2–4% of the introduced quantity was detected in the soil profile of the Luvisols, Kastanozems, and Regosols one day after the start of the experiment. After a year it disappeared to 0.02–0.1%. Clay soils absorb 70–90% of incoming UDMH and sandy soils adsorb 2–46%. The degree of UDMH desorption depends on the granulometric composition, e.g., about 2.7% of UDMH is washed away from the topsoil horizons of clay soils, and about 30% of the total amount of substances is washed away from sandy soils at the first rain [868, 869].

The penetration of UDMH, assumed to be a viscous liquid, through aerated soil was modeled to determine the penetration depth of UDMH spilled on the ground [870]. The penetration was modeled as a function of time, depth, and soil type.

During a study of the adsorption and decomposition of UDMH in red soil and yellow-brown soil, the adsorption curves and adsorption isotherms of UDMH in the two soils were obtained using an improved equilibrium method. The adsorption coefficients were calculated based on the measurement of the adsorption of UDMH in different concentrations [871]. It was found that formaldehyde was a degradation product of UDMH in the two soils. Its concentration changed with time.

Ninety-six samples of peat bog soil from the impact area of the first stage of the CYCLONE-3 launch vehicle containing unburned UDMH in the European North of Russia, near the Plesetsk Cosmodrome, were taken at different distances from the center of the impact area and from different soil horizons [872]. Samples were analyzed by HPLC with amperometric detection and gas chromatography-tandem MS. The contents of UDMH and the ten most important products of its transformations (MMH, hydrazine, 1,1,4,4-tetramethyltetrazene, formaldehyde, acetaldehyde and furaldehyde *N,N*-dimethylhydrazones, 1-formyl-2,2-dimethylhydrazine, *N,N*-dimethylformamide, NDMA, and MTA) were determined. The obtained data reflected the spatial distribution, migration, and transformation of UDMH in the impact area of rocket stages under conditions of sub-arctic climate.

Considerable amounts of UDMH and most of its transformation products were found at distances of <10 m from the center of the impact area. The maximum concentration of UDMH was found near the center where the maximal permissible concentration was exceeded 2400-fold. The worst pollution was observed in the surface soil layer, while methylhydrazine, MTA, 1-formyl-2,2-dimethylhydrazine, formaldehyde and acetaldehyde *N,N*-dimethylhydrazones, and *N,N*-dimethylformamide were the major UDMH transformation products. The composition of the transformation products changed in favor of the last three compounds with increasing distance from the center. Formaldehyde *N,N*-dimethylhydrazone and *N,N*-dimethylformamide were present in all soil samples and can be used as reliable markers of contamination with rocket fuel. The surface water of the peat bog contained four UDMH transformation products in considerable concentrations, including NDMA. The processes of migration and transformation of UDMH in peat bog soil differ considerably from those in sandy soils. This is due to the cold climate of the sub-arctic zone, the reducing environment of peat bog, and strong binding of hydrazines to the organic matter of peat which prevents the migration of pollutants and contributes to the long-term survival of high levels of soil pollution [873].

### 1.9.3 Bioremediation of UDMH Pollution in Soil

Microbial communities of soil bacteria sustainably functioned at UDMH doses of up to 20 mg/kg. When the concentration of UDMH was greater than 200 mg/kg over two weeks of incubation, bacterial activity was completely suppressed [874, 875]. UDMH concentrations of up to 10 mg/kg in soil had no notable impact on the ammonification and nitrification [876].

For bioremediation of UDMH-contaminated soil, Russian scientists decided to work with the bacteria *Rhodococcus* (also referred to as “red ball”), while their Kazakh colleagues selected *Azotobacter* as one of the most promising bacteria types. The possibility of microbiological live culture cleaning of water and soil polluted with UDMH was studied. Several isolates (bacteria, yeast, and micromycetes) capable of utilizing UDMH as the only source of nitrogen, carbon, and energy were isolated from UDMH-polluted tundra soil. Acceleration of UDMH biodegradation was achieved by using a biosorbent that involved cells of the active degrader strain immobilized on granulated activated charcoal [877]. Thus, polluted water could be recirculated through a trickle tower packed with the granulated material. Biological testing in *Escherichia coli* and cereal plants (wheat and barley) demonstrated that biodegradation significantly decreased the toxicity of solutions containing UDMH, suggesting its utility for microbiological cleaning of polluted territories.

In addition to the application of microbes for bioremediation of contaminated soil, Kazakh scientists proposed that polluted areas be planted with amaranth. According to their data, this plant possesses a definite ability to accumulate UDMH (heptyl) from the soil. The plant crop can then be simply cut and destroyed by burning.

The biodegradation rate and pathway of UDMH, when contacted with two strains of bacteria isolated from acclimated activated sludge, were investigated in solution and in soil [878]. The purpose of this study was to provide a fundamental practical way for the bioremediation of soil and water contaminated by UDMH spills at ambient temperature. The results demonstrated that *Stenotrophomonas* sp. M12 (M12) was able to degrade UDMH of 50 mg/L as the sole carbon source in an aqueous mineral salt medium (MSM) but could not degrade UDMH in soil. *Comamonas* sp. P4 (P4) barely degraded UDMH at 50 mg/L as the sole carbon source in aqueous MSM. However, the degrading capacity of P4 could be improved by the addition of an extra carbon source. Meanwhile, P4 was able to degrade UDMH at levels of 100–600 mg UDMH/kg soil. The degradation of UDMH in the soil was influenced by organic matter, autochthonous micro-organisms, and metal ions. UDMH could inhibit the metabolism of M12 and P4, and the inhibition influence was more severe in aqueous MSM than in soil. Oxygen content was important for M12 biodegrading UDMH, and co-metabolism helped P4 to self-detoxify and self-recover. The main intermediates of UDMH were identified by GC/MS, and the concentrations of UDMH and its important transformation products were determined in solution and soil.

A properly designed retaining pond and adjoining artificial wetland inoculated with active sludge sewage treatment bacteria can effectively remove UDMH and degradation products from wastewater [879].

UDMH in the air and in water can be effectively removed using a biofilter with an active bacteria culture. It was proposed to pass a UDMH-contaminated air stream through a biofilter packed with compost-scoria-sugarcane bagasse as the nutrient [683]. The filter was tested at different inlet loadings ( $0.44\text{--}2.68\text{ g m}^{-3}\text{ h}^{-1}$ ) and with various retention times (30, 60, and 90 s), bed heights, and non-ionic surfactants over 126 d. The single-pass removal efficiency was 88%. Dominant species of bacteria in the biofilter bed included *Pseudomonas*, *Acinetobacter*, and *Proteus spp* (see also [880]).

### 1.9.3.1 Degradation of NDMA in Air and in Soil

NDMA is one of the more persistent autoxidation products of UDMH. As such, it can sometimes still be found long after all UDMH and other hydrazines are gone. NDMA degradation in soil, water, and the air is an important aspect of UDMH and DMA toxicity. DMA is a natural product of decaying processes and is part of agricultural and fish industry waste. In highly polluted atmospheres, it forms NDMA during the night, but during the daytime the half-life time of NDMA in the air in full sunlight is only 0.5 h [881].

NDMA, *N*-nitrosodiethylamine, and *N*-nitrosodi-*n*-propylamine were resistant to degradation in soil, sewage, and lake water [882]. No degradation of these nitrosamines was observed in lake water over a three-and-a-half-month period. A lag of nearly 30 d occurred before their slow disappearance from soil. They disappeared slowly from sewage, but a minimum of 50% remained after 14 d. Soil samples were injected with 50 and 250 ppm NDMA and incubated for 25 d. In the first few days, NDMA content dropped rapidly (possibly due to volatilization), then only gradually for the last 20 d. Eight-day soil bacteria cultures did not show any NDMA being digested. The levels of three nitrosamines, including NDMA, decreased slowly over the course of 14 d in sewage adjusted to pH 6. Comparisons of raw versus sterilized sewage suggested some bacterial activity in the degradation of NDMA. The concentrations of three nitrosamines added to littoral water did not change during a 108-d experiment. Nitrosamines are found in cattle manure, DMA in the air surrounding sewage treatment and fish processing plants, and nitrous fumes in silage and automobile exhaust. In summary, there are many sources for the natural formation of nitrosamines. It is difficult to separate biological and physicochemical degradation mechanisms in soil.

#### 1.9.4 Effects of UDMH on Plant Growth

When the concentration of UDMH in soil reached 1.0 g/kg, the growth, development, and productivity of plants initially was stimulated. At values from 1.0 to 10 g/kg, some growth and productivity indicators decreased and the period of development increased. At values from ten to 50 g/kg, the condition of the plant significantly deteriorated. When UDMH concentration is  $\geq 100$  g/kg, the plants die [883].

Undiluted hydrazine, UDMH, or Aerozine-50 was moved through a 20-in. soil column while being leached with 9 in. of water. The soil in the column was sub-divided and each zone analyzed separately [855]. Toxic concentrations of the test chemicals, as measured by the growth of rice, remained in the 12- to 20-in. depth zones of soil even after 9 in. of water had been leached through the columns. All test compounds (at concentrations of  $>200$  ppm) were toxic to the germination and growth of rice, alfalfa, endive, or peas. Hydrazine, UDMH, and Aerozine-50 were toxic to pinto beans at concentrations  $>50$  ppm in water cultures and  $>0.3$  mg/m<sup>3</sup> as fumigants in air. In water, the 24-h median tolerance limit ( $TL_m$ ) values for goldfish, catfish, and bass ranged from 2.4 to 3.7 ppm for hydrazine, from 4.8 to 9.0 ppm for UDMH, and from 3.4 to 6.6 ppm Ae-50.

Vegetation changes at the first stage impact sites of Proton-M rocket launch vehicles were characterized during two growing seasons [884]. Spontaneous re-vegetation by ruderal plant communities occurred after the event. First stage impact sites had lower vegetation cover and species diversity. After winter rocket launches, the vegetation was less deteriorated at the impact sites than after spring and summer launches. The recovery process in plant communities was considerably faster at impact sites corresponding to winter rocket launches. The nitrate fertilizer from NTO/water reactions might help with the re-growth of plants.

### 1.9.5 History of Environmental Pollution by UDMH

#### 1.9.5.1 UDMH Pollution Sites in the US

One of the most complex environmental pollution clean-up tasks in the US was faced by the clean-up contractors for the Hydrazine Blending and Storage Facility at the Rocky Mountain Arsenal near Denver, CO. The facility was constructed in 1959 and operated for 23 years from 1959 to 1982. This facility processed an average of 900 metric tons (1.98 million lb) of Aerozine-50 per year between 1972 and 1975 [358, 359]. The primary activity at the site was the blending of hydrazine and UDMH into Aerozine-50 in support of the TITAN-II and -III programs. In early 1982, OSHA surveyed the site and detected the presence of airborne NMDA within the facility. Several clean-up contractors surveyed the site, continued to take air, soil, and groundwater samples, and proposed remedial action for the 300000 gal of contaminated rinse water still stored at the site. The mountain of paperwork generated as part of these activities is intim-

idating and overwhelming and was in fact causing issues of pollution itself due to paper pollution occurring while the propellant contamination problem was cleaned up. Instead of proceeding to solve the problem, numerous plans were published and re-published in preliminary, draft, preliminary draft, and not so preliminary draft versions. Ten years later, the site still remained on the US Superfund list.

Several decontamination techniques were used to clean up the stored process waste and tank-rinse water [586]. Significant NDMA levels persisted in the groundwater below the Rocky Mountain Arsenal for many years after the propellant mixing facility was shut down [885]. Intercept wells have been sunk to prevent the polluted groundwater from diffusing off-site. NDMA-contaminated water collected in these wells could not be cleaned by activated charcoal filters alone.

At the height of the cold war, there must have been hundreds of NIKE AJAX anti-aircraft missile sites with JP-X Type II all over the US and Europe, and apparently some were still in South Korea as of the mid-1990s. Some JP-X fuel was spilled and not properly cleaned up. Many of these former military sites have since been converted for community use, such as into parks and schools. There have been incidences where the sites were contaminated by leaked UDMH fuel and in a few instances, buried fuel canisters have been found. Unfortunately, no measurements of the persistence of UDMH or NDMA in the soil were made.

#### **1.9.5.2 Use of UDMH in the Former Soviet Union**

Production plants for UDMH in the former Soviet Union existed in Salavat (in the Bushkir Republic) and Angarsk (in the Irkutsk oblast) in the vicinity of substantial human populations. While the main concern is about Proton launches from Baikonur in Kazakhstan [886–888], similar concerns are about the impact of vehicles launched from other sites in Russia such as Plesetsk [889, 890], but not all rockets launched there carry UDMH. Estimates for the total amount of UDMH that may have been produced in the USSR at one time were provided earlier but need to be updated [891]. It was very difficult to keep track of the surplus UDMH after most of the ICBMs using it were decommissioned and demilitarized.

Table 20 is a summary of USSR launch vehicles containing UDMH. The O/F ratio may differ for the first and upper stages, but for the time being one may assume an average O/F ratio of 2.6 which corresponds to 28 mass-% of UDMH in the propellant mass. The list does not include submarine-launched missiles (e.g., SHTIL) because they are less likely to cause pollution on land. In addition, there are several third and kick stages using UDMH but they are not included in this list because they do not contain as much propellants as the first and second stages and they are less likely to impact the ground. In 2006, 16 PROTON M launches were made from the Baikonur spaceport. The first stage of the launch vehicle usually falls on the sparsely populated territory of the Ulytausky area.

**Table 20:** Propellant loads of USSR/Russian launch vehicles and missiles.

| Designation              | Number of stages | Propellant mass, metric tons |              |             | Years of operation | No. of launches                     |
|--------------------------|------------------|------------------------------|--------------|-------------|--------------------|-------------------------------------|
|                          |                  | First stage                  | Second stage | Third stage |                    |                                     |
| TSIKLON-2                | 2                | 118.7                        | 48.5         | —           | 1967–1999          | 109                                 |
| TSIKLON-3                | 3                | 118.7                        | 48.5         | 3.0         | 1977–1999          | 116                                 |
| PROTON-K                 | 4                | 419.4                        | 156.1        | 46.6        | 1967–1999          | 260                                 |
| PROTON-M                 | 4                | 428.3                        | 157.3        | 46.6        | 2000–present       | 102                                 |
| STRELA, SS19 ICBM        | 2                | ~80                          | ~14          | —           | 2003–2014          | Three as satellite launcher         |
| ROCKOT, SS19 ICBM        | 3                | ~80                          | ~14          | 4.9         | 1999–2019          | 146 + 31 as satellite launcher      |
| DNEPR, SS-18 Mod4, R-36M | 3                | —                            | —            | —           | 2000–2015          | Military + 22 as satellite launcher |
| KOSMOS 3M                | 2                | 81.9                         | 18.7         | —           | 1964–1999          | 420                                 |

Data sources: [892].

KOSMOS 3M used RFNA-27N<sub>2</sub>O<sub>4</sub>, not NTO with UDMH. That oxidizer works with a different O/F ratio. Fifty-two SS-18 missiles that were deployed for 30 years in Kazakhstan were transported to the Nizhniy Novgorod region between 1995 and 1996 where they were destroyed [565]. A total of 6000 metric tons of UDMH was transported to Russia for disposal. The US assisted in this effort by providing multimodal tank cars. During the same period, 130 SS-19 missiles were transported to Russia from the Ukraine. The fate of the UDMH contained in those missiles (about 4000 metric tons) remains unknown. Liquid propellant from decommissioned missiles was collected at special facilities located in Piban Shur (Republic Udmurtiya), Surovatikha (Nizhniy Novgorod oblast), Pashino city (Novosibirsk oblast), Krasnash (Krasnoyarsk), and Sergiev Posad (Moscow oblast).

### 1.9.5.3 UDMH Pollution Sites in Russia and Kazakhstan

In a study of populations of two villages directly under the line of flight of launched missiles and near the site of first stage impacts in the Arkhangelsk oblast, it was reported that 79–90% of inhabitants displayed pathologies. In each case, liver damage was observed in more than 50% of the surveyed inhabitants [893]. This is not a peer-reviewed publication.

Since the late 1990s, the ongoing debate about the consequences of the rocket launch activities for the health of people residing near areas of impacts of spent rockets continues [894]. Some scientists argued that the main cause of increased morbidity in those communities is the fault of spilled UDMH. However, field analyses

found UDMH only in the immediate vicinity of fallen carrier rocket fragments. More accurate data were obtained from perennial epidemiological and hygienic research [895]. A hygienic assessment of the nutritional status and health risk of people living near impact areas, and of contaminants in water, soil, and food was performed. A relationship between revealed diseases and UDMH could not be established but there was some causality due to the influence of environmental and psychological anxiety factors that were characteristic of territories and living conditions [896].

For many years, Russia has re-purposed decommissioned SS-19 ICBMs into rocket satellite launchers because it has a stockpile of SS-19s left over from the 1980s and the cold war. Using re-purposed missiles enables Russia to compete in the commercial space launch market, which yields foreign currency. The launches were marketed through Eurokot Launch Services, a joint venture of the Ariane Group and the Khrunichev Space Center. As of 2018, the company's activities were on hold until further notice. Rockets also provide low-cost launches for Russian military satellites. There was concern that residual fuel in re-entering first and second stages could survive the fiery re-entry and contaminate arctic ocean areas that are used by commercial fisheries [546]. There have not been any measurements of UDMH or NDMA residues in seawater or on drift ice in the areas where debris that survives the re-entry heat is expected to splash into the ocean.

#### 1.9.5.4 UDMH Pollution Sites in Other Countries

Most of the Chinese Long March 3 and 4 launch vehicles use NTO/UDMH but little information is available about contamination at the first and second stage impact areas.

## 2 Properties of UDMH/H<sub>2</sub>O Mixtures

Unsymmetrical dimethylhydrazine has been mixed with various other liquids, mostly other rocket fuels, to achieve desirable propellant properties such as lower freezing points, higher densities, reduced infrared emissions from UDMH flames, or improved cooling capabilities in regeneratively cooled rocket engines. One of the best performing fuel blends was a eutectic mixture of UDMH and MMH with a freezing point of 193 K (−80 °C = −112 °F) but no practical application for it has been found. The most widely used UDMH fuel blend for several decades was Aerozine-50 (Ae-50), a 50 : 50 mixture of UDMH and anhydrous hydrazine. As of 2021, Ae-50 has no remaining known uses so this chapter is mostly for historical purposes. Some applications were found for UDMH at a later stage following the first use of Ae-50, by making a fuel blend of UDMH and hydrazine hydrate called UH-25. As of 2021, the UH-25 fuel blend continues to be used in India.

## 2.1 Physical Properties of UDMH/H<sub>2</sub>O Mixtures

Unsymmetrical dimethylhydrazine mixtures with water have no rocket applications. Usually, the water content of UDMH is minimized and carefully controlled where UDMH is used as a rocket propellant. UDMH/water mixtures are encountered mostly during the production of UDMH. In one case, water was added in the form of hydrazine hydrate.

### 2.1.1 Freezing Points of UDMH/H<sub>2</sub>O Mixtures

The UDMH/water system forms two high-melting hydrates: one with 42% UDMH melting at 243.6 K (−29.5°C), and the other one containing 77% UDMH melting at 242 K (−31°C), which correspond to a pentahydrate and a nonahydrate. The UDMH/water system is one of the systems examined during studies on supercooling of strongly hydrogen-bonded binary systems. The UDMH/water solid/liquid system has been studied using thermal analysis covering the equilibrium-phase diagram and irreversible transformations that take place during warm-up of the supercooled liquid [897]. The monohydrate UDMH•H<sub>2</sub>O melts at 242.5 K. It forms a eutectic with UDMH, containing a water mol fraction of 0.125 and melting at 208.5 K. The region around 20 mol-% UDMH could not be resolved due to very slow rates of crystallization. Measurements of the activation energy and activation barriers for crystallization indicated that crystallization occurs by nucleation (if it occurs at all), and often takes place during warm-up, since the values of the entropy of the activated complex are very large and positive during this stage. A comparative study of the glass-transformation range and the viscosity of these mixtures showed a maximum in their free energies of activation at 20 mol-% UDMH. The data suggested a reaction involving a higher-order hydrate, probably a tetrahydrate UDMH•4H<sub>2</sub>O. The region from 15 to 45 mol-% UDMH in which crystallization does not proceed under ordinary conditions, requires additional investigation.

Freezing point data of UDMH/H<sub>2</sub>O mixtures over the entire range of compositions are tabulated in Table 21 and illustrated in Figure 24. The freezing points of UDMH/water mixtures are also visible along one side of the ternary fuel blend chart provided in Figure 48.

### 2.1.2 Vapor-Phase Composition of UDMH/H<sub>2</sub>O Mixtures

Measured activity coefficients of UDMH/H<sub>2</sub>O mixtures differed widely from those predicted by the Gibbs-Duhem equation [898]. The actual activity coefficient of UDMH in dilute solutions is far smaller than the equation predicts. The low degree of activity of UDMH in dilute solution explains the difficulties experienced in trying to recover it from dilute solution by distillation during UDMH production. Additional measure-

**Table 21:** Unsymmetrical dimethylhydrazine/water freezing points.

| Composition, mass-% |                  | Freezing point |       |
|---------------------|------------------|----------------|-------|

Data source: [56].

ments at reduced pressure (13.5 kPa = 102 mm Hg) of vapor-phase decomposition revealed a high-boiling azeotrope at about 6 mol% UDMH (see also [74]).

Figure 25 shows the vapor-liquid equilibrium of the UDMH/H<sub>2</sub>O system at 1 atm pressure. The azeotrope is not obvious at ambient pressure. More detailed UDMH/water vapor-phase diagrams were developed at three different pressures [109]. The vapor-phase diagram (Figure 26) shows a minimum of interaction and no azeotrope formation.

Figure 27 shows the isobaric vapor-liquid equilibrium of UDMH + water at 0.1013 MPa from experimental data, computational simulation, and the Peng-Robinson Equation of State (EOS) [127]. In contrast to other binary systems, this

**Figure 24:** Freezing point of UDMH/H<sub>2</sub>O mixtures. (Reproduced and modified from [56].)

mixture is azeotropic. The experimental data by Carleton [898] and Ferriol et al. [109] are very similar, however, the phase envelope reported by Carleton is a little wider. The experimental vapor pressure by Ferriol et al. [109] (345.17 K and  $x_{\text{UDMH}} = 0.571$  mol/mol) was used to adjust the binary parameter of the molecular model ( $\xi = 1.3$ ) and of the Peng-Robinson EOS ( $k_{ij} = -0.285$ ). It can be seen in Figure 27 that

 Legend: (x) experimental data by Carleton; (+) experimental data by Ferriol et al.; (•) Elts et al. simulation data with  $\xi = 1.3$ ; (—) Peng-Robinson EOS with  $k_{ij} = -0.285$ .

the results obtained by molecular simulation agreed well with the experimental results on the saturated liquid line but they overestimate the UDMH content on the saturated vapor line for intermediate compositions. In the water-rich region and in the UDMH-rich region, the narrow two-phase envelope is well predicted by simulation, whereas the Peng-Robinson EOS yields a qualitatively different form.

### 2.1.3 Density of UDMH/Water Mixtures

The density and viscosity of UDMH/water mixtures were measured over the entire range of compositions and between 148 and 293 K [101], as summarized in Table 22 and 23 and as illustrated in Figure 28 and 29.

Vapor pressure, density, and viscosity data applied to a chemical association model indicate that the solutions may contain a UDMH monohydrate, a trihydrate, and a UDMH dimer [105].

**Table 22:** Density of UDMH/water mixtures.

| Temperature, K    | 293.15                     | 278.15 | 268.15 | 258.15 | 248.15 |

Data source: [101].

**Figure 28:** Density of UDMH/water mixtures. (Chart created by Schmidt 2020 based on data from [101].)

#### 2.1.4 Viscosity of UDMH/Water Mixtures

Viscosities of UDMH/water mixtures were measured over the entire range of compositions and between 148 and 293 K, as summarized in Table 23 and illustrated in Figure 29. These data are from [101].

Viscosity data indicate that the solutions may contain a UDMH monohydrate, a trihydrate, and a UDMH dimer. The viscosity of UDMH-water mixtures peaks near a UDMH mol fraction of 0.25. The peak is very pronounced at lower temperatures.

The viscosity measurements of Laachach of the UDMH/water system are very similar to earlier measurements by McMillan and Los [897] who had also studied freezing point and viscosity over a somewhat lower temperature range of 243 to 283 K and the entire range of UDMH/water ratios. We chose to display the second viscosity chart with a logarithmic viscosity scale in Figure 30, which allows better observation of the changes at low viscosities. The maximum viscosity in the older set of data (11.1 Ps at 243 K) is substantially higher than the highest viscosity measured by the French authors (0.54 Ps at 248 K).

#### 2.1.5 Electric Properties of UDMH/H<sub>2</sub>O Mixtures

The dielectric relaxation times and static permittivity of the binary mixtures of UDMH and water were determined in supercooled conditions down to 150 K to study the

Data source: [101].

association between UDMH and water in the liquid and solid-state [899]. For each system, these properties can be modeled using chemical associations of the type  $(\text{H}_2\text{O}) \cdot (\text{RR}'\text{NNH}_2)$ , and also using self-associations for pure hydrazines. Permittivity  $\epsilon'$  and dielectric loss factor  $\epsilon''$  define the complex permittivity  $\epsilon = \epsilon' - i\epsilon''$ . Capacitance and dielectric loss factor measurements were taken for eight frequencies (2 MHz, 1 MHz, 400, 200, 100, 40, 20, and 10 kHz) on an automatic micro-processor-based LCR meter. An LCR meter is a type of electronic test equipment used to measure the inductance ( $L$ ), capacitance ( $C$ ), and resistance ( $R$ ) of an electronic component. As spontaneous crystallization occurred upon cooling in a certain range of composition, the relaxation phenomenon could be studied only for the following mol fractions  $\chi$  in UDMH:  $0.15 < \chi < 0.4$  for the UDMH/water system. Data for the temperature dependence of static permittivity were tabulated and graphed. The maximum relaxation time was located near the mol fraction  $\chi = 0.20 - 0.25$  for the UDMH/water mixtures. It was found that the associations involved are a monohydrate and a trihydrate. This behavior is closely related to that observed for viscosity [101].

### 3 Properties of UDMH/N<sub>2</sub>H<sub>4</sub> Mixtures

Several decades ago, the most frequently used UDMH/N<sub>2</sub>H<sub>4</sub> mixture was Aerozine-50 (Ae-50), which contained equal amounts (by mass) of UDMH and anhydrous hydrazine. With this 50:50 mix, one might argue about where it should be discussed in this book; here under UDMH or in a parallel chapter on hydrazine (chapter “Hydrazine” in *Encyclopedia of Liquid Fuels*). We chose to discuss it here because many of its properties (vapor pressure, flash point, toxicity) are dominated by its UDMH content and not by its hydrazine content.

Aerozine-50 was the main hypergolic storable fuel of a bygone era, and it is unlikely that it will ever be used again. Nevertheless, we have assembled physical properties of UDMH/hydrazine mixtures here just in case there should be a revived interest in this fuel.

#### 3.1 Physical Properties of UDMH/N<sub>2</sub>H<sub>4</sub> Mixtures

The most comprehensive summary of the physical properties of Aerozine-50 and its constituents is in a report by the Atlantic Research Corporation [108]. It contains a summary of literature data and new measurements of data in areas where some data was lacking. Many additional user manuals for Aerozine-50 developed for the Titan-II program provide a complete summary of the physical, chemical, and safety properties of Aerozine-50 that are not repeated here in detail because of the decreasing use of Ae-50 in the US [96–98, 900, 901]. The physical properties of Ae-50 are summarized in Table 24.

**Table 24:** Physical properties of Aerozine-50.

| Property                           | SI units                                | Other units                                                              |
|------------------------------------|-----------------------------------------|--------------------------------------------------------------------------|
| Molecular mass                     | 41.805 g/mol                            | 23.92 mol/kg                                                             |
| Freezing point                     | 267.6 K                                 | −5.6 °C                                                                  |
| Boiling point                      | 343 K                                   | 70 °C                                                                    |
| Density at 298 K                   | 0.8987 g/cm <sup>3</sup>                | 56.103 lb/ft <sup>3</sup>                                                |

| Refractive index, $n_D^{25}$       | 1.4393                                  | —                                                                        |

More detailed summaries of the physical properties of Ae-50 are provided in the *USAF Propellant Handbooks, Hydrazine Fuels* [95], from which several of the graphs in this chapter were copied.

It is known that UDMH and hydrazine form strong associations with water and other polar fluids. As such, it was important to study the molecular associations between these [902]. Many of the physical properties of UDMH/ $\text{N}_2\text{H}_4$  mixtures are influenced by intermolecular hydrogen bonding and molecule association in the liquid and vapor phase.

### 3.1.1 Freezing Points of UDMH/Hydrazine Mixtures

Aerozine-50 (Ae-50, A-50), a 50:50 (by mass) mixture of hydrazine and UDMH, melts at 265–267 K (17.6–21.2 °F). There is a eutectic point at 214 K (−74.5 °F) that is close to the UDMH end of the system at 96.7 mass-% UDMH [903, 904]. The melting point profile

**Figure 31:** Melting temperatures of hydrazine/UDMH mixtures. (Reproduced and modified from [95] based on data from McMillan 1967.)

of the binary system N<sub>2</sub>H<sub>4</sub>/UDMH is illustrated in Figure 31. Raw data from a different source are tabulated in Table 25.

Several cases of evaporative freezing of propellant have occurred during static-test-firings of the Apollo Service Module engine (SPS) in a low-pressure environment. Although the freezing caused no apparent operational difficulties, an investigation seemed advisable to define the situation. Ae-50 that is suddenly exposed to vacuum will cool (mainly by evaporation of UDMH), and the remaining hydrazine-rich fuel will freeze at the triple point [905–908]. After freezing is complete, the residual material is nearly pure hydrazine. Similar freezing problems may be encountered with the oxidizer, dinitrogen tetroxide, which freezes at 262 K (–10 °C). Evaporation of Ae-50 in propellant valve seats or narrow passages under space vacuum conditions may clog the tubes and prevent fuel flow. Propellant valve leakage does produce system blockage and is a potential hazard to system operation [909, 910]. Although Ae-50 and MMH are very similar in performance, one advantage of MMH is that it does not freeze as easily as Ae-50 residues in a vacuum.

**Table 25:** Binary system UDMH-hydrazine freezing point data.

| Composition of mixture, Mass-% |           | Freezing point |       |
|--------------------------------|-----------|----------------|-------|
| UDMH                           | Hydrazine | K              | °C    |
| 0.0                            | 100.0     | 274.5          | +1.4  |

Data source: [56].

The freezing/melting points of UDMH/hydrazine mixtures are also visible along one side of the ternary fuel blend chart in Figure 48. The melting point of Aerozine-50, the most important mixture in this system, lies between 267 and 269 K (–6 and –8 °C) depending on the precise composition of the sample.

### 3.1.2 Density of UDMH/N<sub>2</sub>H<sub>4</sub> Mixtures

The density of Ae-50, a 50 : 50 mixture of hydrazine and UDMH, as a function of temperature can be expressed by

$$\rho = 1.17423 - 9.2417 \times 10^{-4} T$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $T$  is the temperature in kelvin. This equation, a composite of data from three different sources, was used to calculate the curve-fitted solid line in Figure 32.

**Figure 32:** Density of Ae-50 as a function of temperature. (Reproduced and modified from [95].)

In the range of 273–313 K and 46–50% UDMH, the density of wet Ae-50 can be calculated from

$$\rho = 1.0249 - 9.550 \times 10^{-4} T - 2.165 \times 10^{-3} U + 1.715 \times 10^{-3} W$$

where  $\rho$  is the density in g/cm<sup>3</sup>,  $T$  is the temperature in °C,  $U$  is the mass-% UDMH, and  $W$  is the mass-% water [91].

Results of density measurements of three UDMH/N<sub>2</sub>H<sub>4</sub> mixtures did not exactly match the predicted density calculated, thus assuming ideal liquid behavior (calculated for ideal solutions shown as a solid line, no partial volumina considered), as illustrated in Figure 33. The densities of binary UDMH/hydrazine mixtures are also visible along one side of the ternary fuel blend chart in Figure 49.

**Figure 33:** Measured and predicted density of UDMH/N<sub>2</sub>H<sub>4</sub> mixtures. (Reproduced and modified from [108].)

### 3.1.3 Compressibility and Velocity of Sound of Aerozine-50

Compressibility is usually derived from velocity of sound (i.e., sonic velocity) measurements. The compressibility of a liquid propellant is an important property when evaluating cavitation in propellant pumps and pogo phenomena that may lead to unwanted resonances. The velocity of sound of Ae-50 as a function of temperature can be calculated from the linear equation

$$c = 2765.3 - 3.8695 T$$

where  $c$  is the velocity of sound in m/s and  $T$  is the temperature in kelvin. These data are illustrated in Figure 34.

The adiabatic compressibility of a liquid can be calculated from its sonic velocity and density using the equation

$$\beta_{\text{ad}} = \frac{1}{\rho c^2}$$

**Figure 34:** Sonic velocity of Ae-50 as a function of temperature. (Reproduced and modified from [95].)

where  $\beta_{\text{ad}}$  is the adiabatic compressibility,  $\rho$  is the density, and  $c$  is the sonic velocity. The adiabatic compressibility of Ae-50 as a function of temperature can be calculated from the linear equation

$$\beta_{\text{ad}} = -5.3196 \times 10^{-5} + 3.2458 \times 10^{-7} T$$

where  $\beta_{\text{ad}}$  is the adiabatic compressibility in  $\text{atm}^{-1}$  and  $T$  is the temperature in kelvin. Data calculated from this equation forms the solid line in Figure 35, and is demonstrated in comparison to data points calculated from the sonic velocity and density of Ae-50.

### 3.1.4 Vapor Pressure of UDMH/Hydrazine Mixtures

The condensation and boiling point curves show that the two compounds do not form an azeotrope. Thus, it should be easy to separate the two compounds by distillation. This task may arise in the recovery and recycling of surplus or contaminated Aerozine-50. The vapor pressure of a nominal 50 : 50 blend (actual composition was 51.0 mass% hydrazine, 48.2% UDMH, 0.5% water) as a function of temperature can be expressed by

$$\log p = 9.55828 - \frac{2820.587}{T} + \frac{181627.9}{T^2}$$

where  $p$  is in mm Hg and  $T$  is in K. The low-temperature data for the temperature range 263–344 K (–10 to 71 °C) derived from this equation are shown in Figure 36. The vapor

**Figure 35:** Adiabatic compressibility of Ae-50 as a function of temperature. (Reproduced and modified from [95].)

**Figure 36:** Vapor pressure of Ae-50 at moderate temperatures. (Reproduced and modified from [95].)

pressure will depend on the amount of ullage in the system because, inevitably, some evaporation occurs that changes the composition of the remaining liquid.

For higher temperatures, between 350 and 550 K, the following curve fit is a better representation of experimental data, which was extended to the critical point:

$$\log P = 5.2379 - \frac{2086.62}{T} + \frac{99387.3}{T^2}$$

where  $P$  is in atm and  $T$  is in K. The high-temperature vapor pressure data calculated from this equation are shown in Figure 37.

**Figure 37:** Vapor pressure of Ae-50 at elevated temperatures. (Reproduced and modified from [95].)

### 3.1.5 Vapor-Phase Composition of Hydrazine/UDMH Mixtures

Figure 38 is a schematic pressure-temperature diagram for the system Ae-50 taken from Figure 3.1 in [108]. Similar diagrams apply to other miscible two-liquid systems. The diagram in Figure 38 consists of six single- or multi-phase regions but does not have numbers associated with the temperature and pressure scales.

The condensed phases are separated from the vapor phase by a two-phase region bounded by bubble-point and dew-point curves. The reason for this is that a two-

**Figure 38:** Schematic pressure – temperature-phase diagram of the UDMH/ $\text{N}_2\text{H}_4$  system.

(Reproduced and modified from [108].)

Legend: V – Vapor; L – Liquid;  $S_I$  – Solid Hydrazine;  $S_{II}$  – Eutectic (approximately 97% UDMH);

PTPI – Pseudo Triple Point I; PTPII – Pseudo Triple Point II; QP – Quadruple Point.

component system generally does not vaporize congruently. Thus, vapor in equilibrium (at the bubble point) with liquid Ae-50 does not have the same composition as the liquid but will have a higher concentration of the more volatile component, UDMH. Similarly, the liquid in equilibrium (at the dew point) with the vapor of Ae-50 composition is richer in the less volatile component, hydrazine. In between the bubble point and dew-point curves, the liquid phase has compositions progressing from Ae-50 to that in equilibrium with gaseous Ae-50. An analogous statement holds for the compositions of the vapor. In between the bubble- and dew-point curves the liquid has compositions progressing from Ae-50 to that in equilibrium with gaseous Ae-50. An analogous statement holds for the compositions of the vapor.

At high temperatures and pressures, the bubble-point and dew-point curves bend over towards each other and meet, forming a loop. The top of this loop corresponds to or replaces the critical point of one-component systems. However, the maximum temperature and maximum pressure for the existence of distinct vapor and liquid phases occur at separate points, the plait point and contact point, respectively. Analogous to the condition at the critical point of a single-component system, the enthalpy of vaporization (heat of vaporization) at the contact point is zero. Fundamental thermodynamics were used in the report to derive an EOS for Ae-50.

The solid phase in region  $S_1$  in Figure 38 is solid hydrazine. Because of the low pressure being considered, the composition of the liquid phase may be assumed to depend on temperature alone.

Figure 39 is an isothermal vapor-phase composition diagram of the UDMH/ $N_2H_4$  system at 311 K. Similar diagrams are available for other temperatures.

**Figure 39:** Liquid-vapor equilibria of UDMH/ $N_2H_4$  at 311 K. (Reproduced and modified from [108].)

The same source contains two more diagrams, one for 353 K and another one for 390 K. Liquid-phase activity coefficients and excess free energies of mixing were calculated for all three temperatures and the entire range of compositions. Temperature-entropy and temperature-enthalpy charts for the binary mixture complemented the set of thermodynamic data calculated for the UDMH/ $N_2H_4$  system.

Isobaric data for liquid-vapor phase equilibria of UDMH/ $N_2H_4$  mixtures were measured in the pressure range of 33 to 101 kPa (250 to 760 mm Hg) [107, 912]. Phase compositions were determined from measurements of the refractive index. The temperature range corresponding to these data was approximately 308 to 385 K (35 to 112 °C).

Vapor pressures, phase equilibria, and equilibrium liquid-vapor-phase compositions in the hydrazine/UDMH system were measured. This allowed one to calculate the enthalpy and entropy of vaporization of Ae-50 [104].

Occasionally, if one is burdened with large quantities of waste or surplus Ae-50 and there is a good use for hydrazine, one may want to separate the two hydrazines by distillation [913] instead of disposing of the propellant by incineration. Because

the two boiling points are so far apart and they do not form an azeotrope, this is a relatively easy distillation task but will require a multi-theoretical-plate distillation column. A distillation curve of Ae-50 in a simple still showed that at 10% the distillate was 86% UDMH, at 50% the distillate was 79% UDMH and at 80% the distillate was 100%  $\text{N}_2\text{H}_4$  [900]. During the distillation the boiling point increased gradually from 338 to 388 K (149 to 239 °F).

New molecular models for hydrazine, MMH, and UDMH were proposed to study the fluid-phase behavior of these compounds. A parameterization of the classical molecular interaction models was carried out by using quantum chemical calculations and subsequent fitting to experimental vapor pressure and saturated liquid density data. To validate the molecular models, vapor-liquid equilibria for binary hydrazine mixtures with UDMH were calculated and compared with experimental data [127]. The vapor/liquid equilibrium of UDMH + hydrazine  $\text{N}_2\text{H}_4$  at ambient pressure is presented in Figure 40. This system is zeotropic (i.e., not azeotropic). The experimental vapor pressure by Pannetier and Mignotte [107] at 346.35 K and  $\chi_{\text{UDMH}} = 0.4717$  mol/mol was used to adjust the binary parameter of the molecular model ( $\xi = 1.01$ ) and the Peng-Robinson EOS ( $k_{ij} = -0.1$ ). It should be noted that the description of the interactions between the Lennard-Jones sites of unlike molecules was, in this case, very close to the standard Lorentz-Berthelot combining rules. Simulation results matched almost perfectly with the experimental data on the saturated liquid

**Figure 40:** Isobaric vapor-liquid-phase diagram of the 1,1-dimethylhydrazine/hydrazine system. (Republished and modified from [127], with permission of ©2012 Elsevier Science and Technology Journals; permission conveyed through Copyright Clearance Center Inc.)  
 Legend: + Hydrazine at 0.1013 Mpa: (+) experimental data by Pannetier and Mignotte; (•) Elts et al. 2012 simulation data with  $\xi = 1.01$ ; (—) Peng-Robinson EOS with  $k_{ij} = -0.1$ .

line. On the saturated vapor line, the experimental data and the simulation results exhibited some scatter but the agreement was reasonable. The Peng-Robinson EOS would yield a qualitatively different form.

Out of the three propellant hydrazines, UDMH is the least sensitive to accidents caused by adiabatic compression of vapor bubbles. Nonetheless, the isentropic compression of UDMH and Ae-50 vapors was examined using real gas behavior and equations of state fitted for UDMH for the appropriate real fluid thermodynamic analysis of compression heating and fuel venting [914]. Similar calculations had been performed earlier for hydrazine and MMH. Propellant grade UDMH may contain 98.0 mass-% UDMH, 0.3% H<sub>2</sub>O, and the remainder related amines, which were mathematically treated as similar to hydrazine. UDMH and Ae-50 are usually stored or transported under a blanket of inert gas (either helium or nitrogen). As such, the fuel mixture would also be saturated with blanket gas. Many operations occur in aerospace applications where this fuel mixture undergoes near adiabatic compression or expansion resulting in greatly differing temperatures of the fuel mixture. To predict peak temperatures under those conditions, the Peng-Robinson EOS was validated for pure UDMH. Following this, the UDMH vapor-phase constant-pressure heat capacity was estimated and compared to other hydrazine family heat capacities. Thermodynamic properties were calculated for UDMH. Mixing rules were identified and the non-ideality of the UDMH-hydrazine mixture in Ae-50 was represented by fitting a temperature-dependent interaction coefficient for the UDMH-hydrazine interaction. Isentropic calculations were then made for a mixture corresponding to Ae-50. For these calculations, the following physical properties of UDMH were adopted:

$T_c = 523 \text{ K}$ ;  $P_c = 59 \text{ atm}$ ; acentric factor  $\omega = 0.361$ . The vapor pressure was calculated from

$$\log p = 6.73578 - 875.89/T - 140001.0/T^2$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in K. For higher temperatures, the vapor pressure was calculated from

$$\log P = 4.9439 - 1659.84/T$$

where  $P$  is the vapor pressure in atm and  $T$  is the temperature in K. The peak temperatures for isentropic compression of Ae-50 vapor or the vapor space above Ae-50 with 3% He were calculated for pressure ratios from 10 to 10000. The peak temperatures for a pressure ratio of 100 were 486 and 491 K, respectively, for the real fluid behavior.

### 3.1.6 Viscosity of Aerozine-50

The viscosity of Ae-50 as a function of temperature in the temperature range 273 to 343 K (0 to 70 °C) can be expressed by the equation

$$\log \mu = -0.28445 - \frac{501.489}{T} + \frac{166602.5}{T^2}$$

where  $\mu$  is the viscosity in cPs and  $T$  is the temperature in kelvin. A curve calculated from this formula is illustrated in Figure 41.

**Figure 41:** Viscosity of Ae-50 as a function of temperature. (Reproduced and modified from [95].)

### 3.1.7 Surface Tension of Aerozine-50

The surface tension of Ae-50 can be calculated from the polynomial equation

$$\sigma = 105.960 - 0.41606 T + 5.3088 \times 10^{-4} T^2$$

where  $\sigma$  is the surface tension in dyn/cm and  $T$  is the temperature in kelvin. The surface tension curve in Figure 42 was derived using this equation. To convert the units from dyn/cm to N/m, multiply the numbers by 0.001.

**Figure 42:** Surface tension of Ae-50 as a function of temperature. (Reproduced and modified from [95].)

### 3.1.8 Thermal Conductivity of Aerozine-50

The following polynomial equation represents the thermal conductivity of liquid Ae-50 over the temperature range of 383 to 425 (10 to 152°C) [95]:

$$\lambda = 7.1983 \times 10^{-4} + 3.7467 \times 10^{-7} T - 1.6736 \times 10^{-9} T^2$$

where  $\lambda$  is the thermal conductivity in  $\text{cal cm}^{-1} \text{K}^{-1} \text{s}^{-1}$  and  $T$  is the temperature in kelvin. The same data in SI units gives the equation

$$\lambda = 0.30118 \times 10^{-1} + 1.5676 \times 10^{-4} T - 7.0023 \times 10^{-7} T^2$$

where  $\lambda$  is the thermal conductivity in  $\text{W m}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin. These data are illustrated in Figure 43. To convert units from  $\text{cal cm}^{-1} \text{K}^{-1} \text{s}^{-1}$  to  $\text{W K}^{-1} \text{m}^{-1}$  multiply the numbers by 418.4.

### 3.1.9 Heat-Transfer Coefficient of Aerozine-50

The process for determining the upper limit for the nucleate boiling of hydrazine  $\text{N}_2\text{H}_4$  in heated tubes was dangerous, and even catastrophic, at times. Adding UDMH to hydrazine, as was done in the Ae-50 fuel blend, significantly reduced the explosion hazard. As such, the heat flux for the surface nucleate boiling of Ae-50 at the upper limit could be safely determined (Table 26).

The heat flux at the upper limit of nucleate boiling was determined for two hydrazine-UDMH mixtures containing 50 and 77% hydrazine, respectively [917]. Nominal test conditions for the 50:50 mix ranged from 3.78 to 7.57 MPa fluid static

Data source: [915,916].

pressure, 9.1–27 m/s fluid velocity, and 311–366 K liquid bulk temperature. The other mix was investigated only over a narrower range from 3.78 to 6.19 MPa and at two bulk temperatures, 333 and 366 K. Testing was done in an electrically heated CRES-347 tube with 6.3 mm outer diameter and 0.22-mm walls. The heated section was 75 mm long. The transition from nucleate to film boiling manifested itself experimentally by a sudden large increase of tube-wall temperature. In most cases, the temperature rise resulted in the loss of tube-wall strength, and the test section would rupture before

heater power could be turned off. The  $q_{ul}$  of the 50:50 mix was typically 65% of that previously determined for pure hydrazine at similar conditions. The  $q_{ul}$  ranged from 229 to 638 cal cm<sup>-2</sup> s<sup>-1</sup> (5.85 to 16.33 BTU in.<sup>-2</sup> s<sup>-1</sup>). The numerical data can be approximated using the equation

$$q_{ul} = 7.86 - 4.93 \times 10^{-3}(p - 1100) + 0.1343(V - 50) - 1.20 \times 10^{-2}(T_L - 160)$$

where  $q_{ul}$  is the upper limit of nucleate boiling in BTU in.<sup>-2</sup> s<sup>-1</sup>,  $p$  the static fluid pressure in psia,  $V$  the fluid velocity in ft/s, and  $T_L$  is the bulk temperature in °F. Ninety-five percent of the test data were within  $\pm 15\%$  of the  $q_{ul}$  dependence calculated using this equation. The mixture containing 77% hydrazine and 23% UDMH had upper limits at 77% of those of hydrazine. Demonstrated upper-limit heat fluxes ranged from  $1.31 \times 10^7$  to  $3.06 \times 10^7$  W/m<sup>2</sup> ( $312\text{--}732$  cal cm<sup>-2</sup> s<sup>-1</sup> =  $8\text{--}18.7$  BTU in.<sup>-2</sup> s<sup>-1</sup>) (see also [918, 919]).

### 3.1.10 Pressurant Gas Solubility in Aerozine-50

Solubility of pressurant gases in Ae-50 in comparison to other hydrazines was already detailed in Table 9.

An analysis of dissolved gases using mass spectrometer resulted in another set of gas solubility data. Helium solubility in Ae-50 can be calculated from a linear regression analysis of NASA data [920]

$$\alpha = -0.0257 + 2.75 \times 10^{-4}p + 8.69 \times 10^{-4}t$$

where  $\alpha$  is the solubility in cm<sup>3</sup> He STP/g Ae-50,  $p$  is the pressure in psig, and  $t$  is the temperature in °F. Converting to SI units would result in the following equation:

$$\alpha = -0.0257 + 3.997 \times 10^{-5}P + 8.69 \times 10^{-4}[(T - 273.15)1.8 + 32]$$

where  $\alpha$  is the solubility in cm<sup>3</sup> He STP/g Ae-50,  $P$  is the pressure in kPa, and  $T$  is the temperature in K. Figure 44 is a plot of Ae-50 bubble-point pressure as a function of 100% helium saturation pressure. However, Figure 44 does not show separate plots for different Ae-50 temperatures. Because the total gas content of the Ae-50 is very low, the apparent effect of temperature on the Aerozine-50 is not as pronounced as the apparent effect of temperature on the N<sub>2</sub>O<sub>4</sub>. Since the temperature effect on the Aerozine-50 bubble point was smaller than the variations encountered when Ae-50 bubble-point readings were repeated, the variations due to the temperature effect could not be accurately determined. The average error for all the Aerozine-50 bubble-point pressure data is  $\pm 6.3\%$ .

Nitrogen gas solubility in Ae-50 measurements was conducted on this hydrazine-UDMH fuel blend (composition 50.9 mass-% N<sub>2</sub>H<sub>4</sub>, 48.6 mass-% UDMH, 0.3 mass-% H<sub>2</sub>O, and 0.2% other soluble impurities) over the temperature range of 300 to 331 K (80.6 to 136.0 °F = 27.0 to 57.8 °C) [911]. The raw and reduced data are listed in Table 27.

**Figure 44:** Ae-50 bubble-point pressure as a function of calculated 100% helium saturation pressure. (Reproduced and modified from [920].)

**Table 27:** Gas solubility of nitrogen in Ae-50.

| Temperature |      | Nitrogen partial pressure |      | Experimental specific gas solubility         | Calculated specific gas solubility           |                                              |
|-------------|------|---------------------------|------|----------------------------------------------|----------------------------------------------|----------------------------------------------|
| °F          | °C   | psia                      | atm  | cm <sup>3</sup> N <sub>2</sub> (STP)/g Ae-50 | cm <sup>3</sup> N <sub>2</sub> (STP)/g Ae-50 | 10 <sup>-4</sup> lb N <sub>2</sub> /lb Ae-50 |
| 80.6        | 27.0 | 284                       | 19.3 | 0.551                                        | 0.552                                        | 6.9                                          |
| 82.0        | 27.8 | 585                       | 39.8 | 1.042                                        | 1.032                                        | 12.9                                         |
| 83.1        | 28.4 | 983                       | 66.9 | 1.609                                        | 1.607                                        | 20.1                                         |
| 95.4        | 35.2 | 286                       | 19.5 | 0.612                                        | 0.616                                        | 7.7                                          |
| 95.0        | 35.0 | 586                       | 39.9 | 1.122                                        | 1.132                                        | 14.1                                         |
| 95.0        | 35.0 | 986                       | 67.1 | 1.753                                        | 1.754                                        | 21.9                                         |
| 113.2       | 45.1 | 237                       | 16.1 | 0.589                                        | 0.587                                        | 7.3                                          |
| 113.4       | 45.2 | 483                       | 32.9 | 1.083                                        | 1.077                                        | 13.5                                         |
| 113.5       | 45.3 | 741                       | 50.4 | 1.550                                        | 1.554                                        | 19.4                                         |
| 113.5       | 45.3 | 989                       | 67.3 | 1.977                                        | 1.981                                        | 24.8                                         |
| 135.7       | 57.6 | 279                       | 19.0 | 0.765                                        | 0.765                                        | 9.6                                          |
| 136.0       | 57.8 | 578                       | 39.3 | 1.425                                        | 1.426                                        | 17.8                                         |
| 136.0       | 57.8 | 975                       | 66.3 | 2.230                                        | 2.225                                        | 27.8                                         |

Data source: [911].

From these data, the following correlation was developed for the gas solubility as a function of temperature and nitrogen partial pressure:

$$\alpha = 1.0264 \times 10^{-3} p + 1.7413 \times 10^{-5} t p + 4.464 \times 10^{-3} p^{1/2} + 1.416 t p^{1/2} - 1.594 p^2$$

where  $\alpha$  is the solubility in  $\text{cm}^3 \text{ n}_2/\text{g Ae-50}$ ,  $t$  is the temperature in  $^\circ\text{C}$ , and  $p$  is the pressure in psia. It has also been attempted to derive gas solubility for binary mixtures of hydrazine and UDMH from statistical thermodynamic considerations [921].

The rate of solution of a gas in a liquid is highly dependent upon the extent of agitation and mixing. Gas diffusion through an immobile liquid can take months to equilibrate. The rate of helium absorption into static Ae-50 can be predicted [922].

### 3.1.11 Thermodynamic Properties of UDMH/ $\text{N}_2\text{H}_4$ Mixtures

Next to hydrazine hydrate, the most widely used hydrazine mixture was (for a long period) the 1:1 mixture of hydrazine with UDMH. The thermodynamic properties of this fuel have been thoroughly investigated as a potential fuel in rocket propellant combinations [104, 108, 150]. The heat capacity of this mixture can be calculated from

$$\begin{aligned} c_p(\text{cal g}^{-1} \text{K}^{-1}) &= 0.51241 + 7.3624 \times 10^{-4} T \\ c_p(\text{J g}^{-1} \text{K}^{-1}) &= 2.14392 + 3.0804 \times 10^{-3} T, \quad T \text{ in K.} \end{aligned}$$

The heat of mixing the equal weight proportions of hydrazine and UDMH at 298 K has been estimated to be  $-15.69 \text{ J/g} = -3.75 \text{ cal/g}$ . This amount must be deducted from the theoretical enthalpy of formation of Aerozine-50 before the number can be used for accurate rocket performance calculations. The heat of mixing as a function of the mol fraction and temperature has been derived from sets of data obtained by two different laboratories using a batch adiabatic calorimeter method, as summarized in Table 28 [923]. The experimental values can be expressed by a polynomial curve fit

$$H = x(1-x)(1288.7 + 3.01 T) + 1966.6 x^2(1-x) - 1297.0 x^3(1-x)$$

where  $H$  is the heat of mixing in  $\text{J/mol}$ ,  $x$  is the mol fraction of hydrazine, and  $T$  is the temperature in kelvin. As shown in the last two rows of Table 28, the polynomial equation represents the experimental values reasonably well. Similar data are available for 308 and 323 K, and can be approximated by the equation

$$H = x(1-x)[2800 + 3(T - 273.15) - 400(1-2x)]$$

where  $H$  is the heat of mixing in  $\text{J/mol}$ ,  $x$  is the mol fraction of hydrazine, and  $T$  is the temperature in kelvin. The heat of mixing of UDMH and hydrazine hydrate, as in UH-25, is  $-206.6 \text{ J/mol}$  for an HH100 mol fraction of 0.2933 [924].

**Table 28:** Enthalpy of mixing of UDMH with hydrazine – measured versus curve-fitted smoothed values.

### 3.1.12 Optical Properties of UDMH/N<sub>2</sub>H<sub>4</sub> Mixtures

The index of refraction of binary hydrazine mixtures can be used as a method of quick quantitative analysis. A calibration curve must be prepared first. A refractometric method of analysis of binary hydrazine-water or hydrazine/UDMH mixtures has been described by Pannetier and Mignotte [151, 926]. Data were measured at two temperatures, 293.15 and 298.15 K, over the entire range of compositions. Only the 298.15 K data has been reproduced here (Figure 45).

The refractive index of N<sub>2</sub>H<sub>4</sub>/UDMH mixtures as a function of composition can be expressed by the following equation:

$$n_D^{20^\circ\text{C}} = 1.4683 - 0.09806X + 0.04685X^2 - 0.0119X^3$$

where  $X$  is the mol fraction UDMH.

## 3.2 Chemistry of UDMH/N<sub>2</sub>H<sub>4</sub> Mixtures

### 3.2.1 Storage Stability of Aerozine-50

Missiles fueled with Ae-50 were designed to remain in service in silos for several decades. It was not planned to exchange propellants periodically. The fuel had to be able to remain in storage without degradation of performance for a long period [927].

### 3.2.2 Radiolysis of UDMH/N<sub>2</sub>H<sub>4</sub> Mixtures

Radiation effects on UDMH and N<sub>2</sub>H<sub>4</sub> mixture propellants were studied by exposing the propellant to integrated gamma ray doses of  $10^7 r$  and  $10^{15} n_f vt = 5 \times 10^{15} n/cm^2$  total integrated flux of fast neutrons [928]. The most significant radiation effect was the formation of a small amount of off-gas from the UDMH/N<sub>2</sub>H<sub>4</sub> fuel mixture that appeared

**Figure 45:** Refractive index of hydrazine mixtures at 298 K. (Reprinted and modified from [151].)

to be a linear function of the total radiation dose. The oxidizer  $N_2O_4$ , which was tested in the same way, was not affected by the radiation.

### 3.2.3 Specifications for UDMH/ $N_2H_4$ Mixtures

The specification requirements for the 50-50 mixture of UDMH and hydrazine per MIL-PRF-27402D are listed in Table 29. The older MIL-STD-1775, *Military Standard, Propellant, Hydrazine-Uns-Dimethylhydrazine 50-50 Blend* (4 Jun 1982) is no longer in effect.

### 3.2.4 Analysis of UDMH/ $N_2H_4$ Mixtures

#### 3.2.4.1 Titrimetric Analysis in Non-Aqueous Solutions

In previous papers [396, 399, 929], Malone presented non-aqueous methods for the determination of  $N_2H_4$  in admixtures with UDMH and secondary amines. These meth-

**Table 29:** Specification requirements for the 50-50 mixture of UDMH and hydrazine per MIL-PRF-27402D.

| Properties                                      | Limits           |
|-------------------------------------------------|------------------|
| Hydrazine (% by weight)                         | 51 ± 0.8 minimum |
| UDMH (% by weight)                              | 47 minimum       |
| Water (% by weight)                             | 1.8 maximum      |
| Total hydrazine, UDMH, and amines (% by weight) | 98.2 minimum     |
| Particulate (mg/L)                              | 10 maximum       |

ods were based on the acid-base titration of the UDMH and amines, using perchloric acid as titrant, after the N<sub>2</sub>H<sub>4</sub> had been rendered neutral with either salicylaldehyde or acetic anhydride [402]. This was a rapid chemical method based on the differential reaction rate method of UDMH/hydrazine (N<sub>2</sub>H<sub>4</sub>), or of MMH/N<sub>2</sub>H<sub>4</sub> with either phenyl isocyanate or naphthyl isocyanate. In alcoholic solution, with ethanolic hydrochloric acid as titrant, N<sub>2</sub>H<sub>4</sub>, MMH, and UDMH all react with isocyanates at about the same rate to form semicarbazides. In anhydrous acetic acid, however, N<sub>2</sub>H<sub>4</sub> and MMH react rapidly (MMH slightly slower than N<sub>2</sub>H<sub>4</sub>) with isocyanates, but UDMH does not react appreciably in less than 2h at room temperature. In an acid medium, phenyl and naphthyl isocyanate react with N<sub>2</sub>H<sub>4</sub>, MMH, and UDMH to form semicarbazide

Under the conditions of the experiment, only the N<sub>2</sub>H<sub>4</sub> and MMH react completely. The UDMH reaction rate is very slow.

Mixed hydrazine or UDMH fuels can be analyzed using GC or conductometric methods in the field [930]. Other field test methods were developed for the determination of N<sub>2</sub>H<sub>4</sub>, UDMH, water, and particulate matter in Ae-50, for the determination of water and particulates in nitrogen tetroxide oxidizers and for NO in 90/10 N<sub>2</sub>O<sub>4</sub>/N<sub>2</sub>O<sub>3</sub> oxidizer.

#### 3.2.4.2 Gas Chromatographic Analysis Methods for UDMH/N<sub>2</sub>H<sub>4</sub> Mixtures

Polyethylene glycol (PEG) 400, 600, and 1000 and a nonylphenol-glycidol ether adduct (NPG-10) on Column Pak T or Anakrom AB were tested as column packing for the separation of Ae-50 constituents and ammonia, water, and DMA contaminants [931]. Thirty percent of PEG-400 on Column Pak T formed more symmetrical and better-resolved peaks than NPG-10. The method recommended in an early MIL SPEC for analysis of hydrazine-UDMH mixtures at one time used a 6-mm × 1-m column packed with 33% PEG (Carbowax 400) on 90–100-mesh AnaKrom B [932].

The most recent revision of this spec now recommends a 60-m × 0.53mm, 1.00μm film thickness Agilent DB-Wax capillary column, a thermal conductivity

detector (TCD) with a split injector, and a glass wool packed split liner [933]. Response factors ("normalization factors") must be determined first by analyzing a mixture of known composition. The retention volumes of hydrazine, MMH, UDMH, SDMH, trimethylhydrazine, and 1-aminoaziridine on PEG-20000 are proportional to the base constant  $pK_a$  of these compounds [934].

A field test method was developed for determining the water content of Titan-II propellants [446]. The salicylaldehyde acidimetric titration method of Malone and Barron [399] for the analysis of mixtures of hydrazine and UDMH was found to be unsatisfactory for some purposes. Although a modification of this method gave better reproducibility, the fact that the overall determination was based on the total amine content led to the need to develop a more accurate and specific method. A gas chromatographic method gave separate numbers for ammonia,  $N_2H_4$ , UDMH, and an unidentified compound (probably methylamine or DMA) [935].

If the GC inlet is made from incompatible or catalytic metals and operated while too hot, the UDMH/hydrazine sample may decompose before it has a chance to be separated in the column and be sensed by the detector at the outlet of the column [936]. The GC method that was later adopted for the MIL SPEC was developed in a laboratory at the Olin Mathieson Chem Corp [931].

### 3.2.4.3 Analysis of UDMH Mixtures with Other Organic Fuels

Mixtures of UDMH, DETA, and water (0.15–9%  $H_2O$ ) were analyzed using a 6.35-mm  $\times$  3.65-m ( $1/4$ -in.  $\times$  12-ft.) column packed with 30% tetrahydroxyethylethylenediamine on 30–60-mesh Chromosorb W. They were also reviewed in comparison to results of a near-IR spectrometric method [408]. Synthetic mixtures with known amounts of water and *n*-butanol as an internal standard were run first to determine the response factor for water. This mixture is similar to Hydyne except that it did not contain any acetonitrile.

SDMH is much more toxic than UDMH and is an unwanted contamination in UDMH. SDMH is formed as a by-product, especially if UDMH is made by the direct alkylation of hydrazine. Alkalizing the support prior to applying the stationary phase resulted in the improved separation of alkylhydrazine mixtures [364, 937]. When the Celite C22 support was treated with KOH in methanol prior to applying Carbowax-400 in chloroform, the column filled with this material provided perfect separation of UDMH and SDMH. A similar column packing coated with KOH after the application of the Carbowax was ineffective for SDMH/UDMH separation but separated UDMH and tetramethyltetrazene (TMTZ). The alkalized column was also capable of separating SDMH, UDMH, TMTZ and NDMA. Three different stationary phases (solid paraffin wax, Silicone oil 702, and Carbowax 400) on alkalized Chromosorb *P* were evaluated for the separation of hydrazine, MMH, ethylhydrazine, propylhydrazine, UDMH, trimethylhydrazine, and tetramethylhydrazine [938]. GC separation of a homologue series of monoalkyl-hydrazines was better on paraffin or silicone oil, but separation of hydrazines with increasing degree of methylation was more effective on carbowax,

which is a more polar stationary phase. This series of tests, comparing GLC retention times to boiling points of hydrazines with various degrees of substitution, very nicely illustrate the effects of affinity between the hydrazines and the stationary phases on retention volumina and separation efficiency.

GC separation of all three propellant hydrazines and aniline (a frequent contaminant carried over in the dehydration process) is possible by using wide-bore (0.53-mm) glass capillary columns coated with cross-linked Carbowax 20M [939]. Wide-bore columns allow separations in typically half the time required for packed columns. They have better sample-size capabilities than capillary columns, which are less than 0.35 mm in diameter. Reliable separation of all four compounds, including in the presence of water and ammonia as contaminants, was achieved by splitless injection, temperature programming from 313 to 403 K at a rate of 10 K/min, with helium carrier gas. A flame ionization detector was used for the trace carbonaceous contaminants in hydrazine, which were detectable down to 10 ppm. Aniline in hydrazine cannot be analyzed very well with packed columns using Amine 220 as described in an older MIL SPEC. On the wide-bore column with cross-linked Carbowax 20M, aniline eluted within 12 minutes, and the peaks were even, very symmetrical, and easy to integrate at levels down to 10 ppm aniline. Polyimide coatings on capillary columns are usually very temperature resistant in the absence of hydrazine. However, the liner in the injection port was destroyed after several hundred injections in contact with hydrazine vapors and had to be removed.

#### 3.2.4.4 Analysis of UDMH in Wastewater and Ground Water

Mixtures of ammonia, hydrazine, UDMH, and DMA such as those typically encountered in the effluents from a Raschig process UDMH production facility can be separated on a 1-m column packed with 30% Carbowax-400 on 90/100 mesh Anakrom B support, even in the presence of water [940]. Complete separation could only be achieved by two separate injections at 333 and 398 K column temperature and isothermal operation. The constituents of the mixture eluted in the sequence ammonia, DMA, UDMH, water, MMH, hydrazine. Higher percentages of water (>90%) caused erratic results.

Hydrazine and UDMH in the wastewater from a propellant manufacturing plant can be analyzed in a packed column with Chromosorb-103 and -101 with a detection limit of 10 ng and a relative error of  $\pm 4.9\%$  [941]. Furaldehyde derivatization improved sensitivity and selectivity and allowed the analysis of traces of hydrazine and UDMH (but not MMH) contamination in ground water [360].

Some ground waters react with hydrazines. It is important to test spike recoveries with actual water samples in addition to making standards with clean, deoxygenated, distilled, or deionized water. Sulfuric acid extracts of contaminated soil were reacted with pentanedione and the derivatives so formed were analyzed by GC [942].

Quantitative analysis of trace concentrations of UDMH transformation products in water requires very sensitive analytical instrumentation and tedious sample prepara-

tion. A simple and automated method for the sensitive quantification of UDMH transformation products in water was developed using headspace SPME in combination with GC-MS and GC-MS/MS [461]. This method is based on the extraction of analytes from the gas phase above samples using SPME and applying a micro-polymer coating followed by a thermal desorption of analytes in a GC inlet. Extraction by 85  $\mu\text{m}$  Carboxen/polydimethylsiloxane fiber at 323 K (50 °C) over 60 minutes provided the best combination of sensitivity and precision. Detection limits of 12 analytes using GC-MS/MS with chemical ionization were about 10 ng/L. This method is simpler, automated, provides lower detection limits, and covers more UDMH transformation products compared to other methods. The method was recommended for assessing the water quality in areas affected by rocket launch activities.

Internal standard and standard addition calibrations were used to achieve good accuracy of the quantification of key environmental degradation and transition products of UDMH [943]. 1-Trideuteromethyl-1*D*-1,2,4-triazole (MTA-*d*3) was used as the internal standard. Internal standard calibration facilitated the control of the matrix effects during the quantification of MTA, *N,N*-dimethylformamide (DMF), and NDMA in soils with humus content <1%. Using SPME at 333 K (60 °C) for 15 minutes with 65- $\mu\text{m}$  Carboxen/polydimethylsiloxane fibers, recoveries of MTA, DMF, and NDMA for sandy and loamy soil samples were 91–117, 85–123, and 64–132%, respectively. The method accuracy could be improved, and a wider range of analytes could be detected by a combination of standard addition and internal standard calibration. The combined calibration approach provided the best accuracies for NDMA, DMF, *N*-methylformamide, formamide, 1*H*-pyrazole, 3-methyl-1*H*-pyrazole, and 1*H*-pyrazole. For the determination of 1-formyl-2,2-dimethylhydrazine, 3,5-dimethylpyrazole, 2-ethyl-1*H*-imidazole, 1*H*-imidazole, 1*H*-1,2,4-triazole, pyrazines, and pyridines, the standard addition calibration method was more suitable.

### 3.3 Handling of Aerozine-50

Several handbooks describe safe handling practices for Ae-50. Most of those handbooks were developed for the TITAN-II missile program [96–98, 944, 945]. This is now only of historical interest.

#### 3.3.1 Transportation of Aerozine-50

During the period when Titan-II missiles were deployed, and for a short while after they were decommissioned, NTO and Ae-50 had to be transported by tanker truck across the US. Similarly, when TITAN-III and TITAN-IV were used to launch satellites, the propellants had to be delivered to Cape Canaveral AFS and Vandenberg AFB. The tanker trucks were accompanied by hazardous materials response teams. All these propellant movements were achieved without any serious accidents or spills. Nev-

ertheless, in order to be prepared for all eventualities, the agencies responsible for the safe transport of hazardous propellants prepared training material, driver certification regulations, and response guidelines for “what if” scenarios. This included the development of a computerized emergency response protocol system for releases of hypergolic propellants, modeling atmospheric dispersion in a computerized hazard response protocol system, and a transportation accident response co-ordination guide.

### 3.3.2 Aerozine-50 Spill Treatment

The rate of evaporation of Ae-50 from shallow pools divided by the pool radius is a linear function of the wind speed [703]. Ammonium carbonate (carbamate) was tested as a spill control to reduce the fire hazard. Although ammonia is evolved, ammonia is less of a fire hazard than UDMH vapor. An aqueous acetate-acetic acid buffer solution with a gelling agent was tested as a spill control and fire extinguishing agent against small spills or fires of Ae-50 and/or dinitrogen tetroxide [946].

A vapor cloud caused by either vaporization or reaction of hydrazine and/or UDMH with NTO, as it was used on the Apollo spacecraft, was analyzed to determine the generation and concentration of toxic products and the safe toxic distances in the case of a spill [947]. It was predicted that the process of vaporization of propellant without reaction creates the largest quantity of toxic products. Assuming that the total quantity of fuel or oxidizer aboard the Apollo spacecraft would be spilled in sand and vaporized during unfavorable atmospheric conditions, it would have resulted in a maximum safe toxic distance of 5.5 km (3.4 miles). This safe toxic distance was considered to be the worst case as the cooling effect of vaporization tends to reduce the actual rate of vaporization. The reaction of hydrazine/UDMH mixtures with NTO will produce a smaller quantity of toxic products, thus reducing the toxicity hazard. When formed and above ambient temperature, these hot products will rise and expand, thus creating a faster rate of product dilution (see also [948–952]).

### 3.3.3 Firefighting of Aerozine-50 Fires

The recommended methods for firefighting of Ae-50 fires are similar to those practiced for the extinguishment of UDMH fires [200, 207, 698, 700, 701]. Halon 1301 (Freon 13B1), carbon dioxide, and water were tested as fire extinguishing agents on Ae-50 or MMH fires. The effectiveness of a Halon 1301 system for inerting the atmosphere of an Apollo spacecraft was tested. The conclusion was that Halon 1301 could provide some protection as an inerting agent for spills of Ae-50, and that it could serve well to extinguish secondary fires of many flight vehicle combustibles. However, it was ineffective in combatting an established fire of Ae-50 and led to toxic combustion products and to visibility-limiting smoke [205, 703]. Two parts by weight of water per part of Ae-50 will inert an Ae-50 spill against ignition in air. In a burning Ae-50 pool, the fuel evaporation rate is approximately  $49 \text{ g s}^{-1} \text{ m}^{-2}$  ( $0.6 \text{ lb min}^{-1} \text{ ft}^{-2}$ ). A well-dispersed flow of water at

$100 \text{ g s}^{-1} \text{ m}^{-2}$  is sufficient for extinguishing a fire. A ten-fold excess of water (10 kg water per kilogram of fuel) is required to inert an Ae-50 spill against hypergolic ignition with NTO. Bromotrifluoromethane (Halon 1301) can be used to inert vapor spaces or to extinguish small fires, however, very high  $\text{BrCF}_3$  concentrations are required (>7% by volume) and the protection is not long-lasting (see also [203, 206, 698, 702]) for open-pan burning tests with UDMH in comparison to fires with other more common hydrocarbon fuels. Foams for firefighting and spill control must be compatible with a wide range of propellants [11].

Although carbon dioxide is ordinarily considered a good fire extinguishant and an inert vapor, it formed a solid when it came into contact with Ae-50 or UDMH. It formed syrupy liquids when it came into contact with hydrazine or MMH. Heat was evolved in each case.

### 3.4 Materials Compatibility with UDMH/ $\text{N}_2\text{H}_4$ Mixtures

In view of the widespread use of Ae-50 during the Titan, DELTA second stage, and Apollo programs, there exists a substantial amount of information on materials compatibility with this propellant [953]. It would require a sizable database to collect all this information and present it in a usable format. The same would also be useful for other UDMH-based propellant blends. Unfortunately, this was not possible during the preparation of this book.

#### 3.4.1 Aerozine-50 Compatibility with Metals

It would be difficult to extrapolate from known materials compatibility information for hydrazine  $\text{N}_2\text{H}_4$  and UDMH to the materials compatibility with Ae-50. In most cases where reliable information was required to make well-informed decisions about the long-term storage of missiles in missile silos, the materials compatibility had to be determined with the actual propellant blend and under conditions at the upper-temperature limit of the operating conditions.

In looking for materials for advanced spacecraft valves, several hundred literature references on 21 different propellants that were in use as of 1967, or were anticipated to be used within the next ten years (including Ae-50) were assembled. However, the reports on pages 1–28 through 1–33 lists only materials and temperatures for compatibility and not the duration of immersion [515]. Similar data were on pages 3–26 through 3–31 of [516].

It is not possible to list all references discussing the materials compatibility of Ae-50; therefore, just a few key references are listed here [900, 944, 954–956]. A hydrazine fuels materials compatibility database would be useful to organize this information in a user-friendly way.

### 3.4.1.1 Brazing Alloys for Aerozine-50

Hydrazine and Ae-50 decomposition caused by brazing alloys and their constituents were measured by capturing and analyzing the ammonia formed [957]. The compatibility of hydrazine or Ae-50 with either the 82Au-18Ni alloy or the pure metals (Au or Ni) was equally poor as soon as the temperature exceeded 430 K (156 °C = 314 °F). The amount of ammonia evolved was taken as the indication of hydrazine decomposition at 330 K. It would have been better to use the amount of nitrogen formed because some of the ammonia may remain dissolved in the propellant.

The heat exchanger used to heat helium with Ae-50 in the propulsion system of the Apollo Lunar Module was constructed of CRES-347 stainless-steel. The nickel-based alloy originally used in the fabrication of this unit was found to be unsuitable, and the gold-based alloys, Palniro 7 and Nioro, were selected as appropriate replacements from a structural standpoint. Palniro 7 and Nioro are trade names of braze alloys of the following composition:

Palniro 7    70% gold, 22% nickel, 8% palladium

Nioro        82% gold, 18% nickel

Exposure of gold-based brazing alloys to Ae-50 and to Ae-50 doped with 0.05% chloride or 0.5% ammonia at 339 K (150 °F) for 48 h did not result in leaching of excessive amounts of gold, nickel, or palladium. Neither gold nor palladium was present in detectable amounts in any of the fuel samples. Nickel was found in detectable amounts in all the fuel samples, including those not exposed to the alloys (blank controls).

Very little (unmeasurable) quantity of gas was evolved with Palniro 7 but a substantial amount of gas was evolved with Nioro [958]. The pressure rise in a manometric vessel was not excessive, even in samples that were deliberately contaminated with 0.5 mass-% chloride ion or 0.5% ammonia.

### 3.4.1.2 Stress-Corrosion Cracking in Aerozine-50

Stress-corrosion cracking has been observed in tanks intended to hold NTO or Ae-50. While NTO is an active contributor to stress-crack propagation, Ae-50 is not. Problems with stress corrosion in Ae-50 tanks were mostly caused by residual cleaning fluids (halogenated solvents) or residual methanol once used as an Ae-50 substitute during dynamic and acoustic testing of propulsion systems in space simulation chambers.

A more detailed investigation has shown that some metals are indeed susceptible to stress-corrosion crack growth in liquid hydrazines. Stainless-steel 410, used as a tankage material in the DELTA 89 vehicle, showed stress-corrosion susceptibility with Ae-50 that was most likely contaminated with carbazic acid by absorption of atmospheric carbon dioxide. However, in tests at the Aerospace Corporation, several high-strength steels, including T-1, HY-140, HP-9-4-20, and 18Ni(200) maraging steels that do stress-corrode in seawater did not show stress corrosion in (presumably pure) UDMH [518].

While pressure testing with methanol in 1966, two Apollo Spacecraft Propulsion System (SPS) fuel tanks failed, prompting the NASA Manned Spacecraft Center to initiate a study aimed at obtaining laboratory verification of the cause of the tank failures. The study included obtaining a quantitative evaluation of the expected performance of the other various Apollo tanks in their test and wetted service environments. As part of this study, NASA issued contracts to perform an investigation of the flaw growth characteristics of the Ti-6Al-4V tankage material [514]. Plane-strain cyclic and sustained load flaw growth characteristics were evaluated for Ti-6Al-4V forgings and weldment heat-affected zones (HAZ) at temperatures ranging from 291 to 316 K (65 to 110 °F) in Ae-50, MMH, and NTO inhibited with 0.49% NO, methanol, Freon MF, and distilled water (with and without sodium chromate additions). The basis for the evaluation was the determination of the threshold stress intensity values (the value below which sustained load flaw growth could not occur) in the various liquid environments. The results showed that sustained load threshold values (in terms of initial-to-critical stress intensity ratios) were relatively high, exceeding 75%, with the exception of three environments: methanol, Freon MF, and (at test temperatures exceeding 302 K [85 °F]), dinitrogen tetroxide. Little or no difference in sustained load behavior was observed between base metal and weld HAZ except in the environment of Freon MF. In this case, the flaw growth was significantly more pronounced in the HAZ than in the base metal. At stress intensity levels below the sustained load threshold value, cyclic load flaw growth rates were quite low and were not considered to be a serious problem. In the case of methanol, the base metal threshold value was 24% of the critical stress intensity. With regard to the failed Apollo SPS fuel tanks, this value indicated that initial flaws as small as about 0.003 in. deep could have grown and caused the failure to occur when exposed to methanol at maximum operating stress.

Despite the known stress-corrosion cracking problem with methanol, methanol has been recommended as flushing fluid for the decontamination of Apollo Service Module Ae-50 tanks (it is assumed that systems thus decontaminated were not expected to fly anymore because there may be residual methanol after flushing and drying) [959, 960].

### **3.4.2 Aerozine-50 Compatibility with Non-Metallic Materials**

There are numerous literature summaries on elastomeric materials compatibility with Ae-50 and other propellants [961]. These are needed for gaskets, O-rings, expulsion bladders, and personnel protection equipment.

Molded parts made from thermoplastic resins can be manufactured in the near-net-shape ultimate dimensions, which require no further machines, thus leading to cost savings. The trouble was that, until recently, very little was known about the compatibility of thermoplastic resins with rocket propellants because many of these materials became available only within the past two decades. Ten engineering ther-

moplastics were tested in anhydrous hydrazine for suitability in an Ae-50 application [962].

#### 3.4.2.1 Propellant Expulsion Diaphragms and Bladders for Aerozine-50

For a propellant expulsion bladder or diaphragm, it is important that the material is strong and flexible, remains flexible under conditions of propellant exposure and radiation exposure, has low permeability to propellant liquid, propellant vapors, and pressurant gases, and does not leach any contaminants into the propellant.

Bladders intended for Ae-50 were initially made of multiple sprayed layers of tetrafluoroethylene (TFE) and fluoroethylene propylene (FEP). TFE was manufactured like a sintered powder metallurgical part by compressing the powder. FEP was similar in character to a true thermoplastic material. The major problem was bladder tearing during 3-axis vibration, especially at the lower temperature range [963, 964].

In the early days of hydrazine flight system development, hydrazine stability in elastomer expulsion devices was measured only in weeks [965–967]. For instance, a butyl rubber expulsion bladder was used on the Ranger-3 spacecraft where storability was proven to be better than nine to thirteen weeks. Although EPR-5 demonstrated no measurable Ae-50 permeation, Butyl-7 allowed 0.7% of the propellant to escape after only 7 d. Among six candidate formulations based on *cis*-1,4-polybutadiene, Butyl-218, Hydropol, or ethylene-propylene rubber (EPR), the latter showed the lowest swelling (16%) after immersion in Ae-50 at 344 K (160 °F) for 30 d. In MMH, *cis*-1,4-polybutadiene swelled 10%, EPR swelled 18%, and butyl rubber swelled 26%.

#### 3.4.2.2 Lubricants for Aerozine-50 Service

Many seals and moving parts (pump bearings) must be lubricated to avoid fretting and reduce friction. Greases qualified for hydrazine and UDMH service can be used for Ae-50 as well.

There was one incident of Ae-50 contamination by leaked hydraulic fluid that was similar to incidents that took place many years later in the hydrazine auxiliary power unit (APU) for Space Shuttle Space Transportation System (STS). In the earlier case, solid contaminants found deposited in the cavity between the fuel pump and the gear box of TITAN boosters were analyzed and identified to be composed primarily of aze-laic acid dihydrazide [968]. This product was shown to have resulted from the interaction of Ae-50 and the hydraulic fluid (MIL-L-7808D1 oil) from the gear box. Its structure was conclusively established by independent synthesis of an authentic sample (see also [969, 970]).

### 3.5 Safety Properties of Aerozine-50

#### 3.5.1 Flash Point of Aerozine-50 in Air

At 1 atm pressure, an Ae-50/water mixture must contain at least 37 mass-% water to produce non-flammable vapors in a Cleveland Open Cup apparatus at 298 K (25 °C), and 48 mass-% water in a Tag Closed Cup tester under the same conditions [703]. Unfortunately, heat is evolved when water is added to Ae-50 so that the liquid temperature increases above that of the surroundings. For this reason, more water is needed initially to produce a non-flammable mixture (because of the elevated liquid temperature). A 2:1 water dilution ratio (i.e., 2 kg of water per kg of Ae-50) was considered adequate to prevent the formation of a flammable mixture following an Ae-50 spill.

The flash point of Ae-50 in the air at atmospheric pressure is 276 K (+3 °C) with the Cleveland Open Cup method and 268 K (−5 °C) with the Tag Closed Cup method. The effect of water dilution on the flash point(s) of Ae-50 is shown in Figure 46. A similar

**Figure 46:** Flash points of Ae-50/water mixtures at atmospheric pressure. (Reproduced and modified from [703].)

chart exists for MMH. For comparison, the Cleveland Open Cup flash point of undiluted UDMH is 257 K (−16 °C).

### 3.5.2 Flammability Limits of Aerozine-50 in Air

The flammability of Ae-50 in the air is mostly dictated by its UDMH component. The lower limit of flammability at 101 kPa and 311 K was observed at 3.0% by volume [971]. The upper limit of flammability at 101 kPa and 366.5 K was found at 98.5% by volume. The minimum ignition pressure was at 4 kPa with an Aerozine-50 concentration of 7.6% by volume (complete evaporation of both fuel components).

### 3.5.3 Auto-Ignition of Aerozine-50 Vapors

When Ae-50 vapors come in contact with N<sub>2</sub>O<sub>4</sub> (NO<sub>2</sub>) vapors in the air, they may ignite spontaneously. In Figure 47, the limits of ignition of Ae-50 vapors under those conditions are shown as a function of the NO<sub>2</sub> concentration in the air it comes in contact with.

**Figure 47:** Vapor-liquid equilibrium temperatures of 50-50 fuel blend required for the spontaneous ignition of the resulting vapors in contact with N<sub>2</sub>O<sub>4</sub>-air mixtures. (Reproduced and modified from [900].)

### 3.5.4 Accident History of Aerozine-50

#### 3.5.4.1 Aerozine-50 Exposure

A rocket test stand supervisor had detected an Ae-50 leak, initially escaped the hazard area to don an acid suit and a gas mask, but then returned to the area to check for other leaks [743, 744]. He later had a strong odor of Ae-50 still adhering to his clothes when he reported to the dispensary. He complained of headache, nausea, and a shaky feeling. His exhaled breath smelled strongly of hydrazines even 2h after the expo-

sure. He exhibited twitching of the extremities and clonic movements. Reflexes were hyperactive. After injecting 200 mg *i. v.* and  $2 \times 200$  mg intramuscularly (*i. m.*) pyridoxine•hydrochloride (PIN-HCl), all symptoms except chest congestion vanished within 20 minutes. He still developed bilateral pulmonary edema in the form of wet rales and tachypnea. Oxygen and isuprel inhalation were given to alleviate this problem. Another technician caught in the same leak event had inhaled excessive amounts of Ae-50 vapor before he was able to put on an air supply. He tried to return to the leak area to offer assistance but was overcome by dyspnea, trembling, and weakness. He developed hyperactive reflexes, high respiration rate, and bilateral pulmonary edema. He also was given 200 mg *i. v.* plus  $2 \times 200$  mg *i. m.* PIN-HCl. His dyspnea improved and his other symptoms abated. The use of acute therapeutic doses of PIN-HCl greatly improved the rate of recovery of the accident victims. Follow-up studies during the next days and weeks showed no permanent ill effects in either of the two patients. In another accident at the same test installation, four workers had to control an Ae-50 leak. Wearing acid suits and gas masks prevented them from suffering pulmonary edema but they still suffered severe nausea and vomiting, which possibly could have been prevented by the immediate use of pyridoxine. This drug was administered later *i. v.* at the onset of vomiting, and the vomiting stopped in 20 minutes.

### 3.5.4.2 Titan-II Missile in a Silo Explosion

The accident with the worst potential consequences was caused by a 9-lb wrench socket dropped accidentally into a missile silo while performing maintenance (to restore nitrogen pressure in the second stage oxidizer tank) in September 1980 near Damascus, Arkansas, where it fell several stories deep, puncturing the fuel tank of the first stage and causing Ae-50 to leak out under pressure [972]. The leaked propellant fumes eventually ignited and the missile exploded as soon as all four of the tanks in both stages were crushed. Oxidizer and fuel came in contact with each other, lifting the 740-ton heavy concrete lid off the silo and throwing it several hundred feet into the air. The nuclear warhead was thrown out as well and later recovered. Fortunately, it did not explode.

## 3.6 Environmental Impact of Aerozine-50

### 3.6.1 Flash Evaporation of Aerozine-50 in Vacuum

If an Ae-50 tank is suddenly vented or breached in a vacuum, the UDMH evaporates first, leaving a cloud of frozen hydrazine snow behind. If both Ae-50 and NTO are released at the same time, the two clouds may ignite as soon as they come in contact with each other and depending on the ambient pressure. To study the reactivity and expansion characteristics of Ae-50 and dinitrogen tetroxide released instantaneously in bulk quantities into low-pressure environments ranging from 0.00001 to 1 atm, experiments were performed in a large vacuum chamber by simultaneously breaking

thin-walled glass spheres, each containing 300 mL of Ae-50 or NTO [973]. Following the breakage of the spheres, high-speed motion pictures and pressure measurements by piezoelectric transducers showed that the liquids dispersed by boiling at the exposed surface, and the resulting cloud of vapor and drops expanded symmetrically. At ambient pressures of 0.1 atm and above, the hypergolically ignited combustion or mild explosion occurred approximately 5 ms after the release (the spheres were 0.5 in. apart). At ambient pressures below 0.01 atm, normal hypergolic ignition did not occur. Instead, a mist of an unknown compound formed and detonated 70 to 180 ms after the release. The detonation occurred when the pressure was a few mm Hg above the original ambient level and apparently was initiated by one of the warm metal surfaces of the steam-ejector pumping system.

### 3.7 Properties of UDMH/N<sub>2</sub>H<sub>5</sub>OH Mixtures

#### 3.7.1 Physical Properties of UDMH/N<sub>2</sub>H<sub>5</sub>OH Mixtures

##### 3.7.1.1 Ternary UDMH/Hydrazine/Water Mixtures

Ternary hydrazine mixtures are made up of constituents that are all liquids at ambient temperature. Such mixtures may occasionally be formed to obtain blends with properties not otherwise achievable with binary mixtures. The UDMH/N<sub>2</sub>H<sub>4</sub>/H<sub>2</sub>O mixtures listed in Table 30 have been formulated to provide one oxygen for every carbon when these mixtures were used as monopropellants.

**Table 30:** Freezing points of ternary UDMH/water mixtures with hydrazine.

| Composition, mass-% |                               |                  | Freezing range, K |
|---------------------|-------------------------------|------------------|-------------------|
| UDMH                | N <sub>2</sub> H <sub>4</sub> | H <sub>2</sub> O |                   |
| 37.5                | 40.0                          | 22.5             | 227–218           |
| 26.8                | 57.1                          | 16.1             | 242               |
| 20.3                | 67.6                          | 12.1             | 252               |
| 17.9                | 71.4                          | 10.7             | 255               |

Data source: [974].

It was hoped that the preferential formation of carbon monoxide would avoid the formation of soot. At the lower temperatures, the mixtures exhibited extensive supercooling, and only a freezing range rather than a freezing point could be determined.

At one point, the European ARIANE-3/-4 rocket switched from pure UDMH as a rocket fuel to a mixture consisting of 75% UDMH and 25% hydrazine hydrate. This mixture is called UH-25 and freezes at 243 K (–30 °C). As of 2021, the Indian Geosynchronous Satellite Launch Vehicle (GSLV) and Polar Satellite Launch Vehicle (PSLV) still use UH-25.

### 3.7.1.2 Freezing/Melting Point of UDMH/ $\text{N}_2\text{H}_5\text{OH}$ Mixtures

The freezing/melting point isotherms in the ternary system of UDMH/hydrazine/water are illustrated in Figure 48. The lowest freezing points are encountered along a line connecting the composition of hydrazine hydrate (64%  $\text{N}_2\text{H}_4$ ) with the UDMH corner on top of the triangle.

**Figure 48:** Melting point isotherms in the ternary system of UDMH/hydrazine/water. (Reproduced and modified from [95].)

### 3.7.1.3 Density of UDMH/ $\text{N}_2\text{H}_4$ / $\text{H}_2\text{O}$ Mixtures

The densities of ternary UDMH/ $\text{N}_2\text{H}_4$ / $\text{H}_2\text{O}$  mixtures are illustrated in Figure 49. The highest densities are encountered near the composition of hydrazine hydrate ( $\text{N}_2\text{H}_5\text{OH} = 64\% \text{N}_2\text{H}_4$ ).

### 3.7.1.4 Vapor Pressure of UDMH/ $\text{N}_2\text{H}_5\text{OH}$ Mixtures

The vapor pressure of UH-25 was measured between 293 and 390 K; the data can be expressed using the following equation [975]:

$$\ln P = 9.6838 - 2661.1/T - 224330/T^2$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

**Figure 49:** Densities of ternary UDMH/ $\text{N}_2\text{H}_4$ / $\text{H}_2\text{O}$  mixtures. (Reproduced and modified from [95].)

The heat of vaporization of UH-25 calculated from this vapor pressure equation is 34.7 kJ/mol, while the additive behavior of an ideal solution would expect it to be 36.5 kJ/mol.

### 3.7.2 Chemical Properties of UDMH/ $\text{N}_2\text{H}_5\text{OH}$ Mixtures

#### 3.7.2.1 Thermal Decomposition of UDMH/ $\text{N}_2\text{H}_5\text{OH}$ Mixtures

The pressure rise rate in a closed bomb at temperatures between 391 and 525 K was measured for hydrazine hydrate, UDMH, and UH-25. The logarithm of the pressure rise rate plotted versus the reciprocal temperature formed an Arrhenius plot and the energy of activation could be derived from the slope of the curve. The energies of activation of the decomposition of UDMH, hydrazine hydrate, and UH-25 were 83.2, 99.7, and 100.2 kJ/mol, respectively [975].

#### 3.7.2.2 Analysis of UDMH/ $\text{N}_2\text{H}_5\text{OH}$ Mixtures

The French satellite launch vehicle Ariane-4 used UH-25, which can be analyzed using GC, IR, and iodometric methods [976].

## 4 UDMH/Organic Amines Mixtures

Alkylamines are cheaper than UDMH yet have similar hypergolic fuel properties. It would therefore be advantageous to mix alkylamines with UDMH to make hypergolic fuel mixtures. The preferred amine to mix UDMH with when making mixed amine fuels is diethylenetriamine, DETA,  $\text{H}_2\text{NCH}_2\text{CH}_2\text{NHCH}_2\text{CH}_2\text{NH}_2$ . Several of these mixtures have been assigned names in the Mixed Amine Fuel (MAF) series. Table 31 is a summary of the compositions of MAF fuels. More detailed physical properties of MAF fuels are available in the *USAF Propellant Handbooks, Hydrazine Fuels* (Units eight to 12) [95]. Diethylene triamine has a higher density than UDMH ( $0.9525\text{ g/cm}^3$  compared to  $0.7861\text{ g/cm}^3$ ), therefore the mixtures too have higher densities than UDMH and can replace it in a launch vehicle design, and provide higher total impulse for the same tankage volume. This was a substantial advantage when the Jupiter-C carrying the first US satellite into space changed its fuel choice from ethanol to U-DETA.

**Table 31:** Compositions of MAF fuels.

| MAF   | UDMH | DETA | $\text{H}_3\text{CC}\equiv\text{N}$ | Other amines | $\text{H}_2\text{O}$ |
|-------|------|------|-------------------------------------|--------------|----------------------|
| MAF-1 | 50   | 39   | 10                                  | —            | <1                   |
| MAF-2 | —    | —    | —                                   | 100          | —                    |
| MAF-3 | 20   | 80   | —                                   | —            | <1                   |
| MAF-4 | 60   | 40   | —                                   | —            | —                    |
| MAF-5 | 29.5 | 50.5 | 20.0                                | —            | —                    |

A MAF fuel blend was once used as the fuel in the LR-44-RM-2/SPARROW III AIM-7E, a pre-packaged air-to-air missile with IRFNA as the oxidizer [977]. The fuel consisted of 40.5% UDMH, 50.5% DETA, and 9% acetonitrile. At that time, the solid propellant motors in use in SPARROW I and SPARROW II were outdated, and more advanced solid propellant units were experiencing difficulty at the ambient temperatures expected when carrying the missiles under the wings at high Mach numbers. Solid propellants at that time could not survive a 6-h soak at 366 K (200 °F) before firing.

The composition and properties of MAF-3 were specified by MIL-P-23686A (dated 18 April 1964) and Amendment I (dated 15 March 1965), which allowed a maximum of 1%  $\text{H}_2\text{O}$ .

MAF-4 was alternately known as “U-DETA” and “Hydyne”; it was used in the North American/Rocketdyne LR64-NA-4 target drone engine and in the Army Jupiter-C satellite launch vehicle. The properties and methods of analysis for MAF-4 were specified in MIL-P-23686A.

The only operational use of MAF-1 as a propellant has been as the fuel in the ASM-N7 A and B (GAM•S3) BULLPUP missiles that were produced in large numbers (close to 20000 missiles for the BULLPUP A version). One version of Bullpup A used the LR58-

RM-2 (later LR58-RM-4) propulsion unit from RMD-Thiokol. The Bullpup B missile, which carried a 1000-lb warhead, was based on the LR62-RM-2 propulsion unit and was approximately three times the weight of the BULLPUP A but was controlled in a similar manner with many common components. Seventeen thousand units of the heavier B version were produced during the 1970s.

Procurement of MAF 1 was covered by MIL-P-23741 A (3), dated 15 April 1964, and included Revision I, dated 15 March 1965. The effect of Revision 1 was to relax the lower limit on density at 25 °C from 0.863 to 0.861 g/mL. One of the advantages of the visual-guided liquid-propelled BULLPUP over solid-propelled missiles was the cleanliness of the exhaust, which made seeing the target possible without obstruction by smoke. The smokeless exhaust of a liquid unit would improve visibility during the firing stage and facilitate visual guidance. It was hoped that a pre-packaged liquid propulsion unit would give substantially increased total impulse and thus improve the missile stand-off distance.

MAF-2 was a rarely used hypergolic fuel mixture consisting of 42.6% propargyldiglycidylamine, (PRODGA),  $\text{HC}\equiv\text{CCH}_2\text{N}(\text{CH}_2\text{OCHCH}_2)_2$ , 48.3% dipropargylglycidylamine, (DIPG A),  $(\text{HC}\equiv\text{CCH}_2)_2\text{N}(\text{CH}_2\text{OCHCH}_2)$ , and 9.1% tripropargylamine (TRIPRAM),  $(\text{HC}\equiv\text{CCH}_2)_3\text{N}$ . The acetylenic triple bond and the oxiridine ring tension added energy to those fuels. The disadvantages of MAF-2 were high viscosity and poor ignition with RFNA. MAF-2 did not contain any UDMH at all. It just happens to be part of the MAF family. Mixed hydrazine or UDMH fuels can be analyzed in the field using GC or conductometric methods [930].

#### 4.1 UDMH/DETA Mixtures

DETA is a high-density, low-volatility amine. It is readily available in industrial quantities. Ten tons of AZ-11, a blend of 89% diethylenetriamine and 11% UDMH, were used during development of the AL SAMUD missile in Iraq during 1998–2002 [978].

##### 4.1.1 Physical Properties of UDMH/DETA Mixtures

The physical properties of U-DETA are summarized in Table 32.

##### 4.1.2 Materials Compatibility with UDMH/DETA Mixtures

Materials compatibility for U-DETA mixtures is essentially the same as for UDMH [979, 980]. Thousands of BULLPUP missiles using MAF-1 as the fuel had been fielded during the 1960s, and several were examined for corrosion after they were decommissioned and unloaded after ten to twelve years in the field. No leakage of the missile tanks was found to have occurred in the ten-year storage period. The degree of corrosion that did occur was considered insignificant and would not affect the functional capability of the missile system. Propellant tanks in BULLPUP missiles were examined

**Table 32:** Physical properties of U-DETA (MAF-4).

| Property                        | SI units                   | Other units |          |
|---------------------------------|----------------------------|-------------|----------|
| Freezing point                  | <189 K                     | <-84 °C     | <-120 °F |
| Boiling point                   | 345 K                      | 71.7 °C     | 161 °F   |
| Vapor pressure at 289 K (60 °F) | 9.06 kPa                   | 68 mm Hg    | 1.3 psia |
| Density at 289 K (60 °F)        | 0.858 g/cm <sup>3</sup>    | —           | —        |
| Viscosity at 298 K (60 °F)      | 0.0196 N s m <sup>-2</sup> | 196 cPs     | —        |
| Flash point                     | 281 K                      | 7.8 °C      | 46 °F    |
| Refractive index $n_D^{25}$     | 1.438                      | —           | —        |

Data source: [178,979].

after extended storage tests [981]. The tightly adherent film observed on the fuel tank interior and propellant exposed component surfaces were analyzed and found to be  $\beta$ -aluminum hydroxide.

#### 4.1.3 Toxicity of Mixed Amine Fuels

Toxicity tests of mixed amine fuel, MAF-1, composed of UDMH 50.5%, DETA 40.5%, and acetonitrile 9.0% were initiated to determine and compare the toxicity of the fuel with those of the separate components [982, 983].

#### 4.1.4 Pool Burning of Mixed Amine Fuels

Pool burning and fire extinguishing tests were conducted with MAF-1 and MAF-3, and their constituents, UDMH and DETA [206, 702]. The major components of MAF-1 and MAF-3 differ very widely in their volatility: UDMH boils at 336 K (63 °C) and DETA at 480 K (207 °C). For the 76 and 122 cm diameter trays, predicted pool-burning rate values exceeded observed averages for the middle half of the burning time by about 15% for MAF-1 and about 50% for MAF-3. Once diluted with water, the puddles were more difficult to ignite. The fire point of MAF-1 at 307 K (34 °C) was 64 vol.-% fuel and the fire point of MAF-3 at 298 K (25 °C) was 63 vol.-% fuel.

#### 4.1.5 Detonability of Mixed Amine Fuels

Hydine is non-detonable. It is insensitive to initiation by booster charges consisting of 50 to 100 g tetryl [178].

#### 4.1.6 UDMH/Silicone Oil Mixtures

A desirable heat flux reduction in regeneratively cooled engines is possible by adding up to 3% silicone oil to the hydrazine-type fuel. As the result of silicone oil combustion, the fire side of the combustion chamber becomes coated with a lining of sili-

con dioxide, which reduces heat transfer [984]. Solubility screening tests of 132 compounds showed that UDMH was the best solvent for silicones, MMH was intermediate, and Aerozine-50 was the worst solvent for silicone [985, 986]. Fuel blends containing 3 mass-% of silicone were subjected to 48 h temperature stability tests and 30 d storage tests. Analytical methods for the high-density acid/UDMH/silicone oil propellant that was at one time used in the Agena upper stage are described in [987].

## 5 UDMH/Kerosene Mixtures

Unsymmetrical dimethylhydrazine had been evaluated as a hypergolizing additive to kerosene JP-4 to render it hypergolic with RFNA or WFNA. There were two types of UDMH/JP-4 blends; one with 17% UDMH and one with 40% UDMH, as specified by Specification MIL-P-26694B. JP-X Type I is a mixture of 60% JP-4 and 40% UDMH and was used in the BOMARC booster [988] and early NIKE anti-aircraft rockets [507]. The later NIKE AJAX missile fuel was JP-X Type II with 17% UDMH in JP-4 [989]. The problem was that small quantities of water absorbed from the air caused the binary solution to break into two phases (similar phase separation problems are encountered with Gasohol in automobiles). The phase diagrams for the ternary system UDMH/JP-4/H<sub>2</sub>O were determined at 251 and 298 K for three different grades of JP-4 [990]. The phase diagrams for ternary systems containing mixtures of UDMH, water, and JP-4 were determined at 250 and 298 K (−9 and 77 °F) for three grades of JP-4 (0, 15, and 27% aromatics). The phase diagrams for UDMH, water, and toluene were determined at 250, 298, and 331 K (−9, 77, and 136 °F). The diagrams showed the amount of water required for the undesirable formation of two phases in any combination of UDMH and JP-4 or toluene. For a mixture containing 17% UDMH in JP-4, only 0.2% water will cause phase separation at 233 K. When the mixture contains 40% UDMH, it will tolerate 1% water at 233 K [991, 992]. The mixture containing 40 mass-% UDMH and 60 mass-% JP-4 had the designation JP-X Type I.

### 5.1 Chemical Properties of UDMH/Kerosene Mixtures

#### 5.1.1 Analysis of UDMH/Kerosene Mixtures

Data presented showed that it is possible to procure JP-4 and UDMH, with both complying with their respective specifications. When blended, however, the mixture fails to comply with the limits of specification MIL-P-26694 [993]. Recommended changes for the 10, 35, and 50% distillation points were 341, 350, and 422 K (155, 170, and 300 °F), respectively.

A rapid manometric procedure was developed for the determination of water and UDMH in rocket fuel mixtures of JP-4 and UDMH [407]. These procedures were specif-

ically designed for use in the field by non-technical personnel and were to be used for surveillance checking of Nike fuels. Water content was determined by measuring the hydrogen pressure developed from the reaction of the water with calcium hydride. UDMH in the sustainer fuel mixtures was determined by measuring the gaseous pressure developed by reaction with nitrous acid.

### 5.1.2 Specifications for UDMH/Kerosene Mixtures

The compositions of JP-X mixtures are specified by Military Specification MIL-P-26694B - Propellant, JP-X (JP-4 + UDMH) [994]. These specifications cover three types of JP-X. The nominal composition limits and purity requirements of these three types of JP-X are listed in Table 33.

**Table 33:** Composition limits and purity requirements of hypergolized kerosene per MIL-P-26694B.

| Constituent            | Distillation limit | Unit              | Type I          | Type II         | Type III      | Analytical method          |
|------------------------|--------------------|-------------------|-----------------|-----------------|---------------|----------------------------|
| JP-4 per MIL-T-5624    |                    | Mass-%            | 40 ± 1          | 17.0<br>± 0.3   | 50.0 ± 2.0    |                            |
| UDMH per MIL-P-25604   |                    | Mass-%            | 59 min.         | 83.0<br>± 0.3   | 48 min.       | Potassium iodate titration |
| Distillation           | 10% point          | °F                | 155 max.        | 245 max.        | Not specified |                            |
|                        | 35% point          | °F                | 170 max.        |                 |               |                            |
|                        | 50% point          | °F                | 300 max.        | 340 max.        |               |                            |
|                        | 70% point          | °F                | 370 max.        |                 |               |                            |
|                        | 90% point          | °F                | 470 max.        | 466 max.        |               |                            |

| Particulate            |                    | mg/L              | 10 max.         | 10 max.         | 10 max.       | ASTM D-2276-65T            |

The ignition properties of this fuel with hypergolic oxidizers will be described in a future *Encyclopedia of Hypergolic Bipropellant Combinations*, in the chapter “Hypergolic Combinations With Nitric Acid.” Even smaller additions of UDMH to kerosenes (insufficient to achieve hypergolic ignition) improve the stability of combustion of kerosenes with WFNA or RFNA [995].

## 6 Other UDMH Mixtures

Ammonia/UDMH mixtures are hypergolic with WFNA, RFNA, and NTO, but the mixture  $\text{NH}_3$ /UDMH required at least 25% UDMH to be hypergolic with NTO.

### 6.1 Vapor-Phase Composition of UDMH/FDMH and FDMH/Water Mixtures

Formaldehyde dimethylhydrazone,  $\text{HC}=\text{N}-\text{N}(\text{CH}_3)_2$ , FDMH, is an intermediate in some UDMH manufacturing processes, a by-product in others, and in all cases a degradation product of UDMH and a potential environmental pollutant. It is therefore of interest to separate FDMH from UDMH and water. Measurements of the equilibrium liquid and vapor compositions versus temperatures at 101 kPa (1 atm) total pressure for the non-ideal system of UDMH/FDMH and FDMH/ $\text{H}_2\text{O}$  showed rather large deviations from ideal liquid-vapor solution behavior [105, 996, 997]. The solution model attributes the non-ideality to the formation of chemical association species which obey Henry's law in terms of actual solution equilibrium mol fractions. For the FDMH(=A)/ $\text{H}_2\text{O}$ (=B) and FDMH(=A)/UDMH(=B) systems, associates of the formula  $\text{AB}_2$  as well as  $\text{A}_2\text{B}$  were identified as likely species, as well as an  $\text{A}_2$  dimer of FDMH. The FDMH/ $\text{H}_2\text{O}$  system shows a minimum boiling azeotrope and a large positive deviation in the excess Gibbs-free energy of mixing.

### 6.2 UDMH/Hydroxyethylhydrazine Mixtures

2-Hydroxyethylhydrazine, hydrazinoethanol, HEH, is a hydrazine derivative that, up to now, had not been used as a rocket propellant. *Encyclopedia of Monopropellants* will present a new application for the nitrate salt of HEH, which is abbreviated as HEHN, when it is used as a monopropellant ingredient in combination with hydroxylammonium nitrate, HAN, as the oxidizer. HEH has a much lower vapor pressure but a much higher viscosity than UDMH or ethylhydrazine. Table 34 shows a comparison of the properties of HEH and UDMH. Thus, it would be desirable to use HEH/UDMH mixtures to lower the vapor pressure of UDMH and to lower the viscosity of HEH.

#### 6.2.1 Physical Properties of UDMH/HEH Mixtures

Physical properties of UDMH/HEH mixtures have been determined for mixtures containing 0–50 mass-% HEH [998].

**Table 34:** Comparison of physical properties of UDMH and HEH.

| Property                                      | UDMH                                 | HEH                                                           |
|-----------------------------------------------|--------------------------------------|---------------------------------------------------------------|
| Molecular formula                             | $(\text{H}_3\text{C})_2\text{NNH}_2$ | $\text{HOCH}_2\text{CH}_2\text{NNH}_2$                        |

### 6.2.2 Density of UDMH/HEH Mixtures

The measured density of UDMH/HEH mixtures at 293 K, as illustrated in Figure 50, can be expressed by the linear equation

$$\rho_{\text{meas}} = 2.97 \times 10^{-3} C_{\text{H}} + 0.79$$

while theoretical mixture densities assuming ideal solution behavior would be calculated by

$$\rho_{\text{theor}} = 2.60 \times 10^{-3} C_{\text{H}} + 0.78$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $C_{\text{H}}$  is the concentration of HEH in mass-%. The measured density is higher than the predicted density, which is a deviation in the desirable direction.

### 6.2.3 Vapor Pressure of UDMH/HEH Mixtures

Appreciable lowering vapor pressures of binary mixtures of UDMH/HEH can be expected via the addition of HEH to UDMH because the difference between the vapor pressures of the two components at room temperature is substantial. Reducing vapor pressure of UDMH through the addition of HEH permits not only easier handling of the propellants but also provides a more effective pump design in applications where the propellant is pumped because it is less likely to suffer from cavitation.

Vapor pressures of binary mixtures of UDMH and HEH at 298 K (25 °C) were determined indirectly by the Clausius-Clapeyron equation and mixing rule. The interaction parameter of enthalpy of vaporization for a binary mixture of UDMH/HEH can be obtained from the geometric mean of both components. Figure 51 shows the changes of vapor pressures for both ideal (Raoult's law) and real solutions at 298 K (25 °C) as

**Figure 50:** Measured and predicted density of UDMH/HEH mixtures at 293 K. (Reprinted and modified from [998], with permission from ©2011 Taylor & Francis Ltd, [www.tandfonline.com](http://www.tandfonline.com).)

**Figure 51:** Measured and predicted vapor pressure of UDMH/HEH mixtures at 298 K. (Reprinted and modified from [998], with permission from ©2011 Taylor & Francis Ltd, [www.tandfonline.com](http://www.tandfonline.com).)

a function of HEH content. Measured and calculated vapor pressure as a function of HEH content can be expressed by the equations

$$p_{\text{meas}} = 168.5 - 299.9 \times 10^{-2} C_H$$

$$p_{\text{theor}} = 167.6 - 143.9 \times 10^{-2} C_H$$

where  $p$  is the vapor pressure in mm Hg and  $C_H$  is the concentration of HEH in mass-%. The measured vapor pressure is lower than the predicted vapor pressure, which is favorable (Figure 51). The deviation is an indication of intense hydrogen bonding between the two molecules in the liquid phase.

#### 6.2.4 Viscosity of UDMH/HEH Mixtures

HEH is extremely viscous, which is a disadvantage for liquid propellants that need to flow through narrow valve and injector passages. UDMH/HEH mixtures have a lower viscosity than HEH that makes the fuel more pumpable and flowable. The curve fitting equations of the measured and calculated viscosity data for UDMH/HEH mixtures shown on page 54 of [998] do not match the data shown in the accompanying graph. The measured viscosity was lower than the predicted viscosity. The deviation is an indication of intense hydrogen bonding between the two molecules in the liquid phase.

**Figure 52:** Measured and predicted viscosity of liquid UDMH/HEH mixtures at 293 K. (Reprinted and modified from [998], with permission from ©2011 Taylor & Francis Ltd, [www.tandfonline.com](http://www.tandfonline.com).)

The viscosity of the mixtures does not increase much until the HEH content exceeds 30% (Figure 52). Deviations of the measured values from predicted results become more pronounced by increasing the mass percentage of HEH, which may be attributed to the non-ideality of the system which can be interpreted as hydrogen bonding between two adjacent molecules in the liquid state. The UDMH/HEH blend has been tested as a hypergolic fuel with NTO and RFNA [999].

### 6.3 UDMH/Hydrazinium Salt Solutions

Instead of water, an oxidizing hydrazinium salt like HN can be added to UDMH/ $\text{N}_2\text{H}_4$  mixtures to lower the freezing point and improve the performance. Some examples are listed in Table 35.

**Table 35:** Freezing points of UDMH-hydrazine-HN mixtures.

| Composition, mass-% |                        |      | Freezing point, K |
|---------------------|------------------------|------|-------------------|
| UDMH                | $\text{N}_2\text{H}_4$ | HN   |                   |
| 37.2                | 23.5                   | 39.2 | 219.3             |
| 33.3                | 31.5                   | 35.2 | 223.2             |
| 30.2                | 37.9                   | 31.9 | 237               |
| 27.6                | 43.3                   | 29.1 | 240.4             |
| 25.4                | 47.8                   | 26.8 | 248.2             |

Data source: [974].

A rarely referenced, mostly forgotten ternary UDMH fuel mixture is MHF-2, consisting of 36.5 mass-% UDMH, 40.2% HN, and 23.3%  $\text{N}_2\text{H}_4$ ; it freezes at 219.3 K ( $-59.9^\circ\text{C}$ ). It was intended as a low-freezing point fuel but was very viscous and lacked thermal stability in comparison to similar blends with MMH instead of UDMH [1000]. The density of MHF-2 in the range of 218 to 333 K ( $-55$  to  $+60^\circ\text{C}$ ) can be calculated from

$$\rho = 1.3201 - 7.552 \times 10^{-4} T$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $T$  is the temperature in kelvin. The viscosity of MHF-2 at 298 K was 6.467 cPs.

## 7 Gelled and Metalized UDMH

The performance of UDMH as a fuel for bipropellant combination can be enhanced by suspending finely distributed metal powders, preferably aluminum or beryllium. To prevent the metal powder from settling during storage, the mixture has to be gelled. The amount of metal that can be added is limited by the increasing viscosity of these blends, which makes them hard to pump and inject into a combustion chamber.

There are numerous patents and reports about gelled MMH. Gelling agents that have been proven to work with MMH may also work satisfactorily with UDMH, but the selection of gelling agents for UDMH and hydrazine  $N_2H_4$  follows different guidelines.

Fumed silica Cab-O-Sil, ethylcellulose, methylcellulose, agar agar, polypropylene glycol, hydroxymethyl cellulose, carboxymethyl cellulose, and clay were tested as gelling agents for UDMH and kerosene [1001]. Agar agar formed only partial gelation at 12% in UDMH. Ethyl cellulose at 17% gelling agent formed only a very thin gel. Carboxymethyl cellulose did not gel. Methylcellulose formed a good gel that could be loaded with 30% 15-micron size Al powder. Lecithin was added as a homogenizer. Thermal stability tests done in sealed glass containers for 90 minutes at 281, 293, 303, 313, and 323 K (8, 20, 30, 40, and 50 °C) did not show any separation, demonstrating its stability over a wide temperature range. But such short laboratory tests are meaningless when the gelled fuel needs to be stored for years.

Experimental studies on UDMH gelation using propellant grade (15  $\mu$ m) and pyrotechnic grade (1.5  $\mu$ m) Al powder at the 500-g batch level showed that gellant (methyl cellulose) concentration could be reduced by 50% using pyrotechnic grade Al [1002]. Methyl cellulose (MC) gellant was added pinch by pinch under mechanical agitation. This was followed by the addition of surfactant (silicone oil) and stepwise addition of Al powder. The pseudoplastic and thixotropic behavior of the gels was studied using a Brookfield viscometer at different rpm. Time intervals and flow rates through capillary die holes, burst pressure tests, and bulk density were measured. UDMH gels loaded with 25–30% Al with both grades of Al were stable, pseudoplastic (shear thinning), and thixotropic (time-dependent shear thinning), but their flow pattern through die holes differed in nature.

Thixotropic gels of UDMH have been prepared using methylcellulose (4.48 mass-%) and agar-agar (0.64 mass-%) chemical gelling agents [1003]. Red fuming nitric acid has been gelled by using sodium silicate (4.25 mass-%). The effect of various parameters like the size of the container, particle size of gellants, and temperature on gelation time of UDMH gelled system has been investigated. The gelation time of UDMH gel was found to increase with the increase in the internal diameter of the container. Gelation time was found to show direct proportionality with the particle size when MC was used as the gellant. In the case of MC, the gelation occurred quickly at higher temperature, whereas the reverse trend was observed when agar-agar gellant was used. To boost the performance of liquid propellants,

metalized gels of UDMH containing Al (10–40 mass-%) or Mg (10–25 mass-%) metal powders have been prepared. The density measurements of virgin and metalized gels revealed that there is a maximum increase of 47% and 19% over virgin gels upon the incorporation of Al or Mg powders, respectively.

Efforts have been made to understand the process of gelation using optical and photomicrographic techniques. Rheological studies on UDMH-methylcellulose gelled systems have been conducted under varying shear rates to measure their flow characteristics [1004]. The gel was found to behave as a pseudo-plastic thixotrope. The viscosity build-up as a function of time has been traced to the point of reaching a firm set gel. The viscosity increased with time rapidly in the beginning and only minor changes were observed thereafter. The effect of temperature and metal (Al or Mg) loading on apparent viscosity of the gelled system has been investigated. Both the apparent viscosity and thixotropic character of the unloaded gel were found to decrease with an increase in temperature. An increase in shear rate decreased the apparent viscosity significantly. The thixotropic character of the metalized gelled systems increased with metal content and they exhibited a shear thinning behavior. Polynomial curve fitting was applied to assess the variation of pseudo-plastic index  $n$  and consistency index  $K$  with temperature and metallization. The results revealed that  $n$  increased with temperature and decreased with metal loading whereas  $K$  showed an opposite trend. The yield value of gelled systems decreased with temperature and increased with metal loading.

Preparation of a gelled UDMH fuel metalized with nano-aluminum was done in two steps [1005, 1006]. First, nano-aluminum was suspended in UDMH using ultrasonic-magnetic agitation. Following this, gelling agent was added under mechanical-magnetic agitation. Tween-80 as a surfactant was added to the fuel to better distribute nano-Al particles in the gel media. Experimental study showed that adding 3% Tween-80 to the gel mixture led to better distribution of nano-particles in the gel, improved homogeneity and stability, and decreased syneresis of the liquid UDMH fuel from the network of the gel. Increasing the surfactant concentration from 1 to 3% reduced the vaporization mass loss during centrifuging tests from 14 to 11%.

Gelling agents that have been shown to be useful for the gelling of ethanol as a rocket propellant can also be used for gelling of UDMH. An experimental comparative investigation on the rheological properties of ethanol and UDMH gels using MC as the gelling agent showed that the gelled fuels were thixotropic in nature [1007]. Gelling agent concentrations of 4.5 mass-% were used for the gelation of ethanol and UDMH. Their apparent viscosity values drastically decreased with shear rate and at higher ambient temperatures. The up-and-down shear rate curves for both gels formed an hysteresis loop that showed no significant change with variations in temperature. The UDMH-MC gel had a very high initial viscosity at lower temperatures (283.5 K) that decreased at higher temperature in the shear rate range covered. The gels started flowing at a nominal shear rate range of 1 to 20  $\text{s}^{-1}$ .

UDMH-based shear-thinning (thixotropic) gelled fuel systems and their rheologic-flow properties, mechanism of formation, metallization using nanometer/micron-size metal powders, performance characteristics, ignition, and combustion behavior were tested, but storage life was not determined. Some of the purported advantages of gelled UDMH fuels were advertised with unsubstantiated claims [1008]. If all those unproven claims were true, gelled UDMH would already have been flying in the armament inventory several decades ago (see also [1009]).

The unsteady combustion of organic gel droplets is different from the quasi-steady combustion of conventional liquid droplets and has a significant influence on the spray combustion-flow field of gel fuel liquid rocket engines and on how to optimize engine design. Based on the unsteady evaporation characteristics inside UDMH organic gel droplets and the micro-molecule structure of organic gel propellants, three types of liquid-phase evaporation models were proposed: the unsteady multi-component evaporation model, the interface tracking multi-phase flow evaporation model, and the discrete element multi-phase flow evaporation model [212]. The unsteady multi-component evaporation model regards the gel droplet as a binary multi-component droplet, in which the gellant inside the gel droplet is equivalent to a species with low volatility and high boiling temperature. In order to depict the shape and location variety of vapor bubbles inside the gel droplets more precisely, the interface tracking multi-phase flow evaporation model regards the gel droplet and the vapor bubble inside it as a single fluid, and uses a level set function to track the interface location of vapor bubbles. In view of mixing and combustion process of the gas-phase surrounding the UDMH organic gel droplets, it was proposed that the finite rate chemical reaction model and the flamelet model should be used for the stagnation ambient and convective ambient condition, respectively.

Bipropellant applications of gelled UDMH with IRFNA or NTO as the oxidizer will be discussed in a future publication, *Encyclopedia of Hypergolic Bipropellant Combinations*, in the chapter on “Hypergolic Combinations With Nitric Acid.”

## 8 Symmetrical Dimethylhydrazine (SDMH)

Symmetrical dimethylhydrazine, SDMH, *N,N'*-dimethylhydrazine,  $\text{H}_3\text{CNHNHCH}_3$ ,  $\text{C}_2\text{H}_8\text{N}_2$ , SDMH, CAS RN [540-73-8], an isomer of UDMH, is **NOT** used as a rocket propellant and its formation as an unwanted, more toxic by-product during production, degradation, and disposal of MMH or UDMH must be avoided. The presence of traces of SDMH as a contaminant in UDMH had been ignored in many UDMH toxicity studies. SDMH is a much more potent carcinogen than UDMH and its unrecognized presence may invalidate the published results of some UDMH toxicity tests. Some of

the animal exposure toxicity tests should be repeated with SDMH-free and NDMA-free UDMH.

SDMH may be needed as a reference compound when analyzing MMH or UDMH rocket propellants for SDMH contamination. This is the only reason why some information on the preparation and properties of SDMH is listed here; otherwise, it would be omitted from this book altogether. However, the vast amount of information on the toxicity of SDMH that is available in the literature is not included here. One of the only scientific applications of SDMH is the deliberate and reproducible induction of cancer in test animals to allow for the effectiveness of anti-cancer treatments to be evaluated.

### 8.1 Preparation of Symmetrical Dimethylhydrazine

The synthesis of SDMH and its dichloride is so fundamental that it has even been included as an educational exercise in organic syntheses [1010]. The method described in that book blocks one position on each nitrogen atom of hydrazine by benzoylation:

followed by methylation with dimethyl sulfate:

and hydrolysis to release the SDMH dichloride:

There are many more methods for the preparation of SDMH described in the hydrazine literature [67].

Aliphatic Schiff's bases and *N*-chloro-alkylamines RNHCl react to form intermediate *N,N'*-dialkyl-diaziridines. This can be hydrolyzed with aqueous hydrochloric acid to form the chlorides of *N,N'*-dialkylhydrazines [1011].

### 8.2 Physical Properties of SDMH

The physical properties of SDMH are summarized in Table 36. SDMH is a slightly stronger base than UDMH, with a  $\text{p}K_a$  of  $9.29 \pm 0.70$ .

**Table 36:** Physical properties of SDMH.

|                                | SI units                 | Other units                 |
|--------------------------------|--------------------------|-----------------------------|
| Molecular mass                 | 60.10 g/mol              | 16.64 mol/kg                |
| Melting point                  | 264.3 K                  | $-8.88 \pm 0.04$ °C         |
| Boiling point                  | 354.6                    | 81.5 °C at 753 mm Hg        |
| Density (at 293 K)             | 0.8274 g/cm <sup>3</sup> | 0.052 lb/ft <sup>3</sup>    |
| Vapor pressure at 298 K        | 9.32 kPa                 | 69.9 mm Hg                  |
| Critical temperature           | 530 K                    | 257 °C                      |
| Critical pressure              | 9.12 MPa                 | 90 at                       |
| Enthalpy of formation, liquid  | +50.6 kJ/mol             | +12.1 kcal/mol              |
| Enthalpy of formation, vapor   | +90 kJ/mol               | +21.5 kcal/mol              |
| Heat of fusion                 | 13.788 $\pm$ 0.02 kJ/mol | 3.2955 $\pm$ 0.005 kcal/mol |
| Heat of evaporation at 298 K   | 39.3 $\pm$ 0.06 kJ/mol   | 9.400 $\pm$ 0.015 kcal/mol  |
| Heat of combustion             | 1981 kJ/mol              | 473.5 kcal/mol              |
| Index of refraction $n_D^{20}$ | 1.4039                   | —                           |

### 8.3 Optical Properties of SDMH

Knowledge of the IR spectra of SDMH will help to identify it as a troublesome contaminant in rocket propellants. The IR spectra of gaseous, liquid, and polycrystalline solid symmetrical dimethylhydrazine and its deuterium analogs have been recorded from 70–4000 cm<sup>-1</sup> [1012]. A comparison of the infrared and Raman spectra of the respective compounds indicated that the liquid phase consists of approximately a 69:31% mixture of *gauche* conformers. An assignment of the observed frequencies based on band positions, relative intensities, and isotopic shifts was presented for both molecular conformations. Although the torsional fundamentals were observed for the molecules in both the gaseous and crystalline states, the bands observed for the solids were more clearly defined and were thus employed for barrier height calculations. The three-fold methyl rotational barrier was calculated to be approximately 13.8 kJ/mol (3.3 kcal/mol), whereas the magnitude of the barrier hindering internal rotation about the N–N bond was estimated to be 20.9 kJ/mol (5.0 kcal/mol). The Raman spectrum of SDMH is quite different from that of UDMH [149, 1013].

### 8.4 Thermodynamic Properties of Symmetrical Dimethylhydrazine

Symmetrical dimethylhydrazine is **not** used as a rocket propellant, so physical property data shown here are mostly for comparison with UDMH and for theoretical studies. The heat of combustion of SDMH was measured at 303.15 K and found to be 1981 kJ/mol = 473.454 kcal/mol, which is very similar to that of UDMH [158]. The heat of vaporization of SDMH is 39.33  $\pm$  0.14 kJ/mol (9.400  $\pm$  0.015 kcal/mol).

## 8.5 Chemistry of SDMH

Oxidation of SDMH leads to azomethane, which is potentially detonable. Energetic, nonvolatile salts of SDMH can be used as propellant ingredients, toxicity notwithstanding [1014]. The thermal decomposition of SDMH is quite different from that of UDMH [1015].

## 8.6 Toxicity of SDMH

There are thousands of publications on toxicity, especially the carcinogenicity of SDMH. On more than one occasion, the results of these studies have been confused with results from UDMH toxicity studies. In many instances, people doing toxicity studies with UDMH failed to verify the absence of SDMH as a contaminant in UDMH that was fed to the biota. In this book, we have not covered studies that dealt exclusively with SDMH. In several of the publications referenced throughout this publication, SDMH happened to be included in studies that dealt with all methylhydrazines (mostly UDMH). As such, SDMH was only included for comparison purposes.

# Ethers

## Ethers

This chapter contains sections on alkyl ethers as rocket fuels. Alcohols and ethers share one element, both possess an oxygen atom in the molecule, and ethers can be made by dehydration of alcohols. Ethers contain an oxygen bridge between two organic groups, typically alkyl groups. Ethers are derived by combining two alkyl groups with an —O— bridge, or by dehydrating two mols of alcohol by removing one mol of water. The oxygen balance of ethers is more negative than that of alcohols, so they should make better fuels. Ethers are only partially miscible with water. Ethers have been tested as rocket propellants but do not offer any advantages over alcohols. Ethers that have been tested as rocket propellants include a cyclic ether, ethylene oxide (oxirane), in monopropellants and vinyl alkyl ethers in hypergolic bipropellants.

### 1 Ethylene Oxide

Ethylene oxide, also known as  $C_2H_4O$ , oxirane, epoxyethane, oxacyclopropane, 1,2-epoxyethane, EtO, CAS RN [75-21-8],  $M = 44.0526$  g/mol, is a heterocyclic aliphatic ether. Its molecular structure is shown in Figure 1.

**Figure 1:** Molecular structure of ethylene oxide

The strained ring structure is the main reason for the high enthalpy of formation and the ease of thermal decomposition of this compound, which is why it was once considered as a monopropellant; see the chapter “Organic Monopropellants” in *Encyclopedia of Monopropellants*. Here, we only summarize its physical and chemical properties and a few academic studies of its decomposition kinetics. Ethylene oxide decomposition gas generators were once tested as turbine drives to drive the oxidizer and fuel pumps in large rockets. It would have been a replacement for hydrogen perox-

ide, which is usually used to generate the hot steam needed to drive these propellant pumps. Ethylene oxide is not commonly used as a rocket fuel.

Ethylene oxide vapor is widely used for the sterilization of medical equipment and for the fumigation of grain in storage silos. It was estimated that the total world consumption in 2002 was  $14.7 \times 10^6$  metric tons, about 73% of which went into the production of ethylene glycol. Other derivatives of ethylene oxide include glycol ethers, ethanolamines, and surfactants. Ethylene glycol for polyester production is still a firm market. Additional information on ethylene oxide can be found in common reference encyclopedias [1, 2].

### 1.1 Production of Ethylene Oxide

Ethylene oxide is made by direct oxidation of ethylene using a silver catalyst. Historically, ethylene oxide was first made from chlorohydrin with alkali, but this process is no longer used. Ethylene oxide is an important intermediate in the syntheses of many industrial chemical compounds, mostly glycols and other polyols [3]. As of 1983, 12 companies produced ethylene oxide in the United States and Puerto Rico using four different technologies at 15 different locations.

### 1.2 Physical Properties of Ethylene Oxide

The physical properties of ethylene oxide are summarized in Table 1. At room temperature, EtO is a colorless gas. It condenses at  $283.8\text{ K} = 10.7^\circ\text{C}$  into a colorless liquid. The liquid can be stored at room temperature under its own vapor pressure, but it is usually stabilized by addition of carbon disulfide or pyrogallol to prevent unwanted polymerization.

An empirical fundamental equation of state correlation was developed for ethylene oxide [5]. The correlation is explicit in terms of the Helmholtz energy and can be used to calculate all thermodynamic properties. The underlying dataset consisted of experimental and molecular simulation data. The experimental data almost exclusively covered the gaseous phase and were available for temperatures from the triple point up to the critical point. Molecular simulation data were used to extend the validity to the liquid state and up to a maximum temperature of 1000 K and a maximum pressure of 700 MPa.

The vapor pressure of ethylene oxide can be calculated from the Antoine equation

$$\log P = A - [B/(T + C)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. Values for the constants  $A$ ,  $B$ , and  $C$  are available for two different temperature ranges, as shown in Table 2.

**Table 1:** Physical properties of ethylene oxide.

| Property                                                 | SI units                                 | Other units   |
|----------------------------------------------------------|------------------------------------------|---------------|
| Molecular mass                                           | 44.0526 g/mol                            | 22.700 mol/kg |
| Freezing point                                           | 160.6 K                                  | −112.5 °C     |
|                                                          | 160.55 K                                 | −112.6 °C     |
| Boiling point                                            | 283.8 K                                  | 10.7 °C       |
| Density (at 293 K)                                       | 0.8711 g/cm <sup>3</sup>                 | —             |
| Coefficient of thermal expansion (at 328 K = 55 °C)      | 0.00161/°C                               | —             |
| Vapor pressure (at 293 K = 20 °C)                        | 146 kPa                                  | 1095 mm Hg    |
| Dynamic viscosity (at 273 K = 0 °C)                      | $3.2 \times 10^{-4}$ N s m <sup>−2</sup> | 0.32 cPs      |
| Dynamic viscosity at boiling point                       | $2.8 \times 10^{-4}$ N s m <sup>−2</sup> | 0.28 cPs      |
| Surface tension (at 293 K = 20 °C under pressure)        | $2.43 \times 10^{-4}$ N/cm               | 24.3 dyn/cm   |
| Refractive index ( $n_D^{20}$ ), liquid, at 280 K = 7 °C | 1.3597                                   | —             |
| Dielectric constant (at 272 K = −1 °C)                   | 13.9                                     | —             |
| Critical temperature                                     | 468.9 K                                  | 195.8 °C      |
| Critical pressure                                        | 7.23 MPa                                 | 72.33 bar     |

Data sources: [3, 4]

**Table 2:** Values for the constants in the vapor pressure equation for ethylene oxide.

| Temperature range, K | A       | B       | C       | References |
|----------------------|---------|---------|---------|------------|
| 182.59–283.59        | 4.386   | 1115.1  | −29.015 | [6]        |
| 273.4–304.9          | 5.84696 | 2022.83 | 62.656  | [7]        |

Another vapor pressure equation for ethylene oxide for the range 199.3–469 K (−73.8 to +196 °C) used four coefficients and the equation

$$\log p_V = A + \frac{B}{T} + C \log T + DT$$

where  $p_V$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. The correlation constants are  $A = 40.723$ ,  $B = -2372.6$ ,  $C = -12.865$ , and  $D = 7.3243 \times 10^{-3}$ . For a temperature of 298 K, this equation gives a vapor pressure of 1297 mm Hg [8].

The dynamic viscosity of liquid ethylene oxide in the range 223–273 K can be calculated from the following equation:

$$\mu = 4.189 \times 10^6 T^{-2.923}$$

where  $\mu$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The viscosity at 273 K is 0.320 cPs [9].

The dynamic viscosity of liquid ethylene oxide in the range 160–468 K (–113 to +195 °C) can be calculated from the following equation:

$$\log \eta = A + \frac{B}{T} + CT + DT^2$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The coefficients for this equation are  $A = -1.678$ ,  $B = 312.4$ ,  $C = 0.03232 \times 10^{-2}$ , and  $D = -0.7838 \times 10^{-6}$ . For example, the viscosity from this equation at 298 K is 0.25 cPs [8].

The surface tension of ethylene oxide at 243.2 K is 32.65 dyn/cm and at 298 K (under pressure) it is 23.21 dyn/cm.

The thermal conductivity of ethylene oxide as a saturated liquid can be calculated from the equation

$$\lambda = A + BT + CT^2$$

where  $\lambda$  is the thermal conductivity in  $\mu\text{cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin. The correlation constants for ethylene oxide in the temperature range 160–453 K (–113 to +180 °C) are  $A = 626.62$ ,  $B = -79.51 \times 10^{-2}$ , and  $C = -2.85 \times 10^{-4}$  [10]. At 293 K (+20 °C), the thermal conductivity of liquid ethylene oxide under pressure is  $369 \mu\text{cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1}$ .

The thermal conductivity of ethylene oxide vapor can be calculated from the polynomial equation

$$\lambda_G = A + BT + CT^2 + DT^3$$

where  $\lambda_G$  is the thermal conductivity of ethylene oxide vapor at low pressure (approx. atmospheric pressure) in  $\mu\text{cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin. The correlation constants for ethylene oxide in the temperature range 273–1273 K (0 to 1000 °C) are  $A = -34.84$ ,  $B = 12.96 \times 10^{-2}$ ,  $C = 3.63 \times 10^{-4}$ , and  $D = -18.26 \times 10^{-8}$  [8].

### 1.2.1 Molecular Structure of Ethylene Oxide

The atom distances in the ethylene oxide molecule are C–C = 0.1466 Å, C–H = 0.1085 Å, and C–O = 0.1431 Å. The H–C–H bond angle is 116.6° and the C–O–C bond angle is 61.64°.

The potential energy hypersurface for two interacting rigid ethylene oxide molecules was created by computing the second virial coefficient, shear viscosity, and thermal conductivity of the gas [11]. The values of these properties were substantiated by the best experimental data as they tended to fall within the uncertainty intervals and obeyed the experimental temperature functions, except for viscosity, where experimental data were insufficient. Due to the lack of reliable data, especially for the transport properties, calculated values were the most accurate estimates for these properties of ethylene oxide available at that time.

### 1.2.2 Infrared Spectrum of Ethylene Oxide

The IR spectrum of ethylene oxide is shown in Figure 2.

**Figure 2:** Infrared spectrum of ethylene oxide. (Reproduced and modified with permission from [12])

### 1.2.3 Thermodynamic Properties and Thermal Properties of Ethylene Oxide

Thermodynamic properties of ethylene oxide are summarized in Table 3.

**Table 3:** Thermodynamic properties of ethylene oxide.

| Property                                                               | SI units                                     | Other units                                             | References |
|------------------------------------------------------------------------|----------------------------------------------|---------------------------------------------------------|------------|

|                                                                        | $1306.0 \pm 0.59 \text{ kJ/mol}$             | $312.14 \text{ kcal/mol}$                               | [13]       |

For additional information on thermodynamic properties of EtO, see [4, 14, 15].

### 1.2.3.1 Heat Capacity of Ethylene Oxide

The heat capacity of gaseous ethylene oxide can be calculated from the Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$ , A, B, C, D, and E are constants, and  $\tau$  is the absolute temperature in kelvin divided by 1000. The coefficients are listed in Table 4. The same coefficients (and others) are used for formulas expressing the standard enthalpy of formation and the standard entropy of the vapor. These equations were obtained by curve fitting data covering the ranges 298–1200 and 1200–6000 K.

**Table 4:** Constants for thermodynamic properties of ethylene oxide vapor.

| Temperature range, K | 298–1200  | 1200–6000 |
|----------------------|-----------|-----------|
| A                    | −23.25802 | 131.3483  |
| B                    | 275.6997  | 13.80594  |
| C                    | −188.9729 | −2.645062 |
| D                    | 51.03350  | 0.175820  |
| E                    | 0.386930  | −30.03639 |
| F                    | −55.09156 | −158.3795 |
| H                    | −52.63514 | −52.63514 |

Data source: [13, 16]

Enthalpy data were determined calorimetrically for both vapor and liquid ethylene oxide from 322 to 422 K (120–300 °F) and 0.345 to 3.723 MPa (50–540 psi) with an estimated accuracy of 2% [17]. Entropy values were derived from the experimental data, and the results were presented in table format and on a  $p$ – $\Delta H$  diagram. Vapor pressures evaluated from the experimental data from 322 to 422 K (120–300 °F) were in reasonably good agreement with values predicted by extrapolating previously published information applicable to lower temperatures.

Another source of data gives the heat capacity of ethylene oxide vapor assuming ideal gas behavior from the polynomial equation [18]:

$$C_p = -7.520 + 2.2206 \times 10^{-1}T - 1.2560 \times 10^{-4}T^2 + 2.5918 \times 10^{-8}T^3$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin.

The heat capacity of liquid ethylene oxide between 161 and 314 K can be calculated from the equation

$$C_p = 79.81 - 2.751244 \times 10^{-2}T + 1.822322 \times 10^{-4}T^2$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin [19]. A similar but older polynomial gives the heat capacity of liquid ethylene oxide between 160.6 and 453 K ( $-112.5$  and  $+180^\circ\text{C}$ ) as

$$c_p = 0.2839 + 2.347 \times 10^{-3} T - 11.66 \times 10^{-6} T^2 + 20.04 \times 10^{-9} T^3$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} ^\circ\text{C}^{-1}$  and  $T$  is the temperature in kelvin [10]. The heat capacity of liquid ethylene oxide at 283 K is  $0.47 \text{ cal g}^{-1} ^\circ\text{C}^{-1}$ .

### 1.2.3.2 Enthalpy of Formation and Heat of Combustion of Ethylene Oxide

The vapor-phase excess enthalpy above the standard enthalpy of formation  $\Delta H^\circ_{f,298}$  of EtO can be calculated from the Shomate equation:

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - H$$

where A, B, C, D, E, F and H are constants and  $\tau$  is the absolute temperature in K divided by 1000. The coefficients are the same as those listed in Table 4. The same coefficients (and others) were used for a formula expressing the heat capacity of the vapor (see above). These equations were obtained by curve fitting data covering the range from 298 to 6000 K. The heat of combustion is  $1306.0 \pm 0.59 \text{ kJ/mol}$  for EtO vapor and  $1262.9 \pm 1.3 \text{ kJ/mol}$  for EtO liquid.

## 1.3 Chemical Properties of Ethylene Oxide

Ethylene oxide is miscible with water over the entire range of mixture ratios. It forms a clathrate with water. It will react with water at higher temperatures and hydrolyze to form ethylene glycol, which is an industrial process for making ethylene glycol, most of which is used as an antifreeze in automobiles. Polymerization of ethylene oxide leads to poly(ethylene glycol). Ethylene oxide is a very good solvent for most polar organic compounds, similar to diethyl ether or dioxane. Lower alkanes do not dissolve very well in EtO; only butane dissolves appreciably.

Once upon a time (long, long ago), when the US Air Force was still considering and testing the use of ethylene oxide as a monopropellant to drive auxiliary power units, the procurement of ethylene oxide was governed by *Military Specification MIL-P-8845 – Propellant, Ethylene Oxide*, which established the contaminant limits listed in Table 5. No document has superseded this specification.

**Table 5:** Contaminant limits in ethylene oxide per MIL-P-8845A.

| Constituent  | Maximum concentration | Method                        |
|--------------|-----------------------|-------------------------------|
| Free acidity | 0.005 mass-%          | Acidimetric titration         |
| Water        | 0.03 mass-%           | Karl Fischer titration        |
| Total iron   | 0.1 mg/L              | Colorimetry                   |
| Aldehydes    | 0.3 mass-%            | Iodine titration              |
| Chloride     | 0.2 mass-%            | AgNO <sub>3</sub> colorimetry |

### 1.3.1 Analysis of Ethylene Oxide

The concentration of EtO vapor in air can be measured using IR spectrophotometric methods [20]. The easiest method of performing occasional spot checks of ethylene oxide concentration in the air in the workplace is to use gas detection tubes containing an indicator (supported on a granular material) that changes color when exposed to ammonia. Such tubes are available from Draeger, MSA, Kitagawa, and others. Gas detection tubes are sensitive to as little as 1 ppm C<sub>2</sub>H<sub>4</sub>O and can measure up to 500 ppm C<sub>2</sub>H<sub>4</sub>O with ten strokes. Draeger ethylene oxide gas detection tubes are available for two ranges of concentrations (Table 6).

**Table 6:** Draeger ethylene oxide gas detection tubes.

| Tube designation       | Concentration range | Draeger part number |
|------------------------|---------------------|---------------------|
| Ethylene Oxide 1/a (5) | 1–15 ppm            | 67 28 961           |
| Ethylene Oxide 25/a    | 25–500 ppm          | 67 28 241           |

Data source: [21]

### 1.3.2 Thermal Decomposition of Ethylene Oxide

The exothermic homogeneous gas-phase decomposition of EtO in the absence of catalysts or contaminants:

starts at 843 K = 570 °C and leads mostly to methane and carbon monoxide in addition to other decomposition byproducts (ethane, ethylene, soot, hydrogen). In the presence of catalysts (Fe<sub>2</sub>O<sub>3</sub>, Raney nickel, unidentified contaminants), the reaction starts at 400 K = 127 °C. The exothermic decomposition of EtO makes this chemical useful as a monopropellant, but it has also been the cause of numerous industrial accidents. Most studies on the decomposition of ethylene oxide have been motivated by the desire to prevent future industrial accidents and not so much by the need to understand the decomposition of ethylene oxide if it is used as a gas generant or a rocket propel-

lant. The equation shown here is only an oversimplified representation of the more complex actual decomposition reaction. The applications of ethylene oxide as a rocket propellant and gas generant are discussed in more detail in a later section on monopropellants (see the chapter “Organic Monopropellants” in *Encyclopedia of Monopropellants*).

### 1.3.2.1 Ethylene Oxide Decomposition Mechanisms and Kinetics

The decomposition kinetics of ethylene oxide are difficult to investigate because the reaction products are not a homogeneous gas mixture, but a two-phase mixture of gases and solid carbon.

The homogeneous unimolecular gas-phase decomposition of ethylene oxide vapor in a Pyrex glass vessel was studied, attempting to avoid wall effects and catalysts [22]. In that work, the slow decomposition of ethylene oxide between 653 and 717 K (380–444 °C) in a Pyrex chamber was studied by measuring the total pressure as a function of time. The reaction was found to be first order and homogeneous, with  $\text{CH}_4$ , CO, and  $\text{H}_2$  as products. The reaction exhibited a considerable induction period that ranged from 1 to 0.5 min at 717 K (444 °C) to 30 min at 653 K (380 °C). The effects of eleven diluents were studied. Ten of them, e.g., carbon dioxide, carbon monoxide, nitrogen, and neon, depressed the rate, but hydrogen increased it considerably.

The thermal decomposition of ethylene oxide exhibited an induction period and was inhibited by the addition of inert gases [23]. Two assumptions – that ethylene oxide mainly isomerizes to acetaldehyde but at the same time produces free radicals that induce chain decomposition of the acetaldehyde, and that the recombination of methyl radicals requires a third body – led to expressions for the length of the induction period and the pressure change during the decomposition experiment that were in qualitative agreement with results from previous investigators.

The rate of EtO decomposition was measured in a Pyrex vessel between 708 and 778 K (435–505 °C) using methods generally similar to those used by Heckert and Mack, and the results agreed quite well with previous data [24, 25]. It was noticed, however, that the total pressure increase for complete reaction fell below 100% at greater temperatures or pressures, with the minimum value being slightly less 80% at 778 K (505 °C). This was explained as being the result of a polymerization process occurring simultaneously with the decomposition. A solid product was formed at high temperatures that subsequently decomposed slowly. See also [26, 27].

The rate of disappearance of EtO and the rate of formation of decomposition products can be monitored by IR absorption spectrophotometry [28].

The thermal decomposition of ethylene oxide in a stream of helium was analyzed by a mass spectrometer [29]. The decomposition of 1 mol of ethylene oxide created 0.6 mol of methyl free radicals.

The thermal decomposition of ethylene oxide vapor was studied in the temperature range from 623 to 713 K (350–440 °C) and at pressures from 24 to 58 kPa (180–440 mm Hg) [30–32]. The disappearance of ethylene oxide was determined by analyzing the unreacted ethylene oxide. In agreement with previous investigations, the experiments indicated that the reaction is approximately first order. The rate at 673 K (400 °C) was reduced to 46% of its normal value by the addition of propylene, which acted as a free-radical scavenger. The reaction in the presence of propylene was first order. The activation energies for the reactions with and without added propylene were 240 and 220 kJ/mol (57.4 and 52.7 kcal/mol), respectively. Formaldehyde, acetaldehyde, and acrolein were detected in small quantities in the reaction products. When the surface:volume ratio in the reactor vessel was increased, the reaction mechanism remained unchanged.

In a flow reactor designed for the study of reaction kinetics at high temperatures, the rates of decomposition of ethylene oxide were measured up to temperatures approaching its adiabatic decomposition temperature (~1200 K) [33–36]. The reaction process was followed not by the freezing (quenching) technique usually employed in flow systems, but by tracing the temperature history of the reaction. The ethylene oxide decomposition study showed that the kinetics followed a first-order mechanism overall, and the overall activation energy was  $176 \pm 8$  kJ/mol ( $42 \pm 2$  kcal/mol). The results were independent of the amount of fuel injected, the velocity of the inert carrier gas, and the inert gas itself. A free-radical decomposition mechanism consistent with the experimental results was postulated.

It was postulated that the pyrolysis of EtO proceeds via internal isomerization (similar to that of isoelectronic cyclopropane) to form an excited  $(\text{CH}_3\text{CHO})^*$  molecule [37]. It was estimated that the excess energy of this molecule is about 356 kJ (85 kcal), which is about 29 kJ (7 kcal) in excess of the C–C bond dissociation energy in an unstrained molecule such as  $\text{CH}_3\text{CHO}$ . The lifetime of  $(\text{CH}_3\text{CHO})^*$  for bond fission is very short, so it is predominantly quenched at  $P \geq 26.7$  kPa (200 mm Hg). Analysis of the chain mechanism indicated a chain length of between one and two with the production of a “hot”  $\cdot\text{CH}_2\text{CHO}$  radical formed by exothermic ring opening of EtO. This is likely to be quenched but may decompose spontaneously to  $\text{H}_2\text{C}=\text{CO} + \cdot\text{H}$ . Published data on high-temperature reactions (1100 K) give absolute rates in reasonable accord with the 700 K reaction. The lower values of  $E_{\text{act}}$  found at the higher temperatures may not be reliable. Data on the pyrolysis of a similar oxirane, propylene oxide, were in good agreement with this model.

The homogeneous decomposition of EtO was studied in a steady-flow microreactor constructed of gold and operated differentially at atmospheric pressure and from 763 to 963 K (490–690 °C) [38]. The reactant was diluted with more than 70% helium to prevent runaway reactions. The conversion of EtO was kept to below 10%. Space velocities were varied from 0.7 to  $23 \text{ s}^{-1}$ , and EtO partial pressures were varied from 2.27 to 94 kPa (17–705 mm Hg). Decomposition products included acetaldehyde, CO,  $\text{CH}_4$ ,  $\text{C}_2\text{H}_6$ ,  $\text{H}_2$ , and traces of  $\text{C}_3\text{H}_8$ . The pre-exponential factor of  $2.4 \times 10^{13} \text{ s}^{-1}$  is what

one would expect for a unimolecular reaction. The activation energy of 226 kJ/mol (54 kcal/mol) is consistent with isomerization of EtO to an excited acetaldehyde fragment  $\text{CH}_3\text{CHO}^*$ , which either decomposes unimolecularly to methyl and formyl radicals or collides with the wall and rids itself of excess energy to become acetaldehyde, which decomposes further. The activation energy for ring opening of EtO is 218 kJ/mol (52 kcal/mol).

Decomposition waves in liquid ethylene oxide were investigated both theoretically and experimentally with an emphasis on near-critical conditions, where the liquid surface within the wave approaches its thermodynamic critical point [39]. Wave velocities, temperature distributions, and sample conditions required for ignition were measured for pressures of 2.4–24 MPa. Predictions were made of flame properties, liquid surface conditions, and critical combustion conditions. Laminar waves were observed for pressures of 6–16 MPa, and turbulent waves were observed at higher pressures. In the laminar regime, wave velocity was a linear function of pressure, indicating a global second-order reaction. Heated or fused wires were used as ignitors since ignition energies were in excess of 8 J. Film boiling occurred along the wires prior to ignition for subcritical conditions. Both predictions and measurements indicated that critical liquid-phase combustion occurs at pressures of 12–16 MPa, which also corresponds to the pressure range where that sample temperatures required to initiate decomposition abruptly decrease. Reduced convective heat loss from the ignitor in the near-critical region was suggested as the mechanism for this behavior.

### Computational Chemistry Studies of Ethylene Oxide Decomposition

The unimolecular decomposition of ethylene oxide (oxirane) and the oxiranyl radical was examined by molecular orbital calculations and detailed kinetic modeling of ethylene oxide pyrolysis in a single-pulse shock tube [40]. It was found that the largest energy barrier to the decomposition of ethylene oxide lies in its initial isomerization to form acetaldehyde, and, in agreement with previous studies, the isomerization was found to proceed through the  $\cdot\text{CH}_2\text{CH}_2\text{O}\cdot$  biradical. Because of the biradical nature of the transition states and intermediate, the energy barriers for the initial C–O rupture in ethylene oxide and the subsequent 1,2-H shift remain highly uncertain. An overall isomerization energy barrier of  $247 \pm 8$  kJ/mol ( $59 \pm 2$  kcal/mol) was found to satisfactorily explain the available single-pulse shock tube data. This barrier height is in line with the estimates made from an approximate spin-corrected procedure. The dominant channel for the unimolecular decomposition of ethylene oxide was found to form  $\cdot\text{CH}_3 + \text{HC}\cdot\text{O}$  at around the ambient pressure. This accounts for >90% of the total rate constant for  $T > 800$  K. The high-pressure limit rate constant for the unimolecular decomposition of ethylene oxide was calculated as

$$k_{1,\infty} = (3.74 \times 10^{10}) T^{1.298} e^{(-29990/T)} \quad \text{s}^{-1}$$

for  $600 < T < 2000$  K.

### 1.3.2.2 Effects of Contaminants on Decomposition of Ethylene Oxide

Catalysts and contaminants (alkaline substances, acids, Lewis acids, anhydrous  $\text{FeCl}_3$ ,  $\text{AlCl}_3$ ,  $\text{SnCl}_4$ ) catalyze the spontaneous decomposition and exothermic polycondensation of EtO. Accidental contact of liquid EtO with such substances must be avoided because it could cause explosive rupture of the storage vessel [41].

Rust is everywhere, so the chances are that rust will accidentally find its way into any ethylene oxide system. Samples of various iron oxides suspended above ethylene oxide in an adiabatic calorimeter exhibited exothermic activity at temperatures as low as room temperature [42]. A  $\gamma\text{-Fe}_2\text{O}_3$  sample was found to show the highest reactivity with ethylene oxide. When in contact with most of the iron oxide fines tested, ethylene oxide displayed exothermic activity below 373 K (100 °C). Self-heating rates near 2000 °C/min were observed for the  $\gamma\text{-Fe}_2\text{O}_3$  fines, while rates in excess of 100 °C/min were found for other fines ( $\alpha\text{-Fe}_2\text{O}_3$  and hydrated  $\alpha\text{-Fe}_2\text{O}_3$ ). In two cases ( $\alpha\text{-Fe}_3\text{O}_4$  and  $\alpha\text{-Fe}_2\text{O}_3$ ), pressurization rates were above 1000 psi/min. Some of these iron oxides might be useful as catalysts for ethylene oxide decomposition reactors in gas generators or rocket engines.

The reactivity of ethylene oxide (EtO) with contaminants such as potassium hydroxide (KOH), sodium hydroxide (NaOH), and ammonium hydroxide ( $\text{NH}_4\text{OH}$ ) was measured using an automatic pressure tracking adiabatic calorimeter (APTAC) [43, 44]. Each contaminant was investigated using three different concentration levels of around 0.10, 0.50, and 1.0 g in roughly 14 g EtO. KOH, NaOH, and  $\text{NH}_4\text{OH}$  had significant effects on EtO thermal stability. Lowering of the onset temperature was observed as the contaminant concentrations were increased.  $\text{NH}_4\text{OH}$  caused the highest reactivity compared to the other contaminants. KOH reduced the onset temperature of pure EtO to near room temperature, even at a low concentration.

An investigation of the reactivity of EtO with various contaminants, including water, different kinds of iron oxides, and alkalis, showed that pure EtO is not prone to initiating a runaway reaction below 473 K (200 °C) under adiabatic conditions, that the possibility that an EtO aqueous solution will experience an exothermic reaction depends strongly on the EtO concentration, and that the onset temperature could be predicted by a fourth-order reaction rate model [45]. EtO exhibited different sensitivities to various kinds of iron oxides. Although  $\gamma\text{-Fe}_2\text{O}_3$  was the most active iron oxide in contact with EtO, its runaway reaction consequence was less severe. The order of reactivity of EtO with iron oxides was  $\gamma\text{-Fe}_2\text{O}_3 > \alpha\text{-Fe}_3\text{O}_4 > \text{hydrated } \alpha\text{-Fe}_2\text{O}_3 > \alpha\text{-Fe}_2\text{O}_3$ . Alkaline materials at sufficient concentrations reduced the initial reaction temperature of EtO to room temperature, and the order of hazard potential for alkalis was:  $\text{NH}_4\text{OH} > \text{KOH} > \text{NaOH}$ .

The unwanted polymerization of EtO can be retarded or prevented by antioxidants [46].

### 1.3.2.3 Catalytic Decomposition of Ethylene Oxide

For the frequently proposed but rarely observed application of ethylene oxide as a monopropellant gas generant or rocket propellant, it would be very useful to have a catalyst that enhances the decomposition of ethylene oxide or even initiates the decomposition at room temperature. Unfortunately, no such catalyst has been identified up to now. The majority of publications on EtO decomposition deal only with homogeneous gas-phase decomposition in the absence of catalysts.

Where ethylene oxide is used for sterilization of medical equipment, the gases leaving the sterilization chambers and vented above the roof have to pass through a catalytic incinerator, where ethylene oxide is destroyed by reaction with excess air. Catalytic incinerators have been the source of ignitions and have caused numerous accidents where combustion has propagated upstream into the sterilization chambers. Catalysts for ethylene oxide incineration with an excess of oxygen in air are different from catalysts aimed at decomposition of EtO as a monopropellant.

Nickel (supported on amorphous Raney nickel or as a single crystal) can decompose ethylene oxide. The adsorption and decomposition of ethylene oxide on single crystals with Ni(110) surfaces at 95–350 K was investigated by LEED and X-ray and UV photoelectron spectroscopy [47]. Thermal as well as photon-induced decomposition was discovered, with X-rays being about ten times more efficient than UV photons under the chosen experimental conditions. A possible reaction pathway involves intermediates, such as methoxy,  $\text{CH}_x$ , and the final (at  $>300\text{ K}$ ) species, CO and carbon. A further possible intermediate, adsorbed acetaldehyde, appeared to be short-lived on Ni(110).

### 1.3.2.4 Suitable Materials of Construction for Ethylene Oxide Systems

Most metals that are commonly used in construction, except copper, silver, magnesium, and their alloys, are suitable for use in equipment in contact with liquid or gaseous EtO. If hardenable steels and other ferrous alloys are used, one must be very careful to remove all traces of rust before the equipment is put in service. The use of stainless steels and pure aluminum ( $>99.6\%$  Al) is preferred.

Gaskets, flex hoses, valve stem packings, and similar applications will use Teflon, Kel-F, nylon, or polyethylene. Copolymers of polyethylene and polypropylene have shown very good compatibility with EtO. Common hydrocarbon-based lubricants are useless because they dissolve readily in liquid EtO. The verdict about the suitability of perfluorinated halocarbon lubricants is not unanimous. Some rate them as permissible, whereas others warn against the use of Kel-F [48].

Liquid ethylene oxide with carbon disulfide as a stabilizer may corrode the aluminum alloy 61S, which is welded and heat-treated to the T-6 condition, differently from pure EtO [49].

For additional information about elastomeric materials of construction that are suitable for use with EtO, see [50].

## 1.4 Handling of Ethylene Oxide

The safe handling of EtO requires special precautions. The handling of EtO is complicated by a combination of a high vapor pressure at room temperature, a wide range of flammability, low initiation energy, autodecomposition, and toxicity.

Ethylene oxide is used in huge quantities as an intermediate in the chemical process industry, so there is a good experience base upon which recommendations for safe handling of EtO can be based.

Ethylene oxide was once evaluated as a monopropellant for auxiliary power gas generators, and the experience from that experiment was documented to help others understand the hazards of working with this chemical [51]. See also [52].

### 1.4.1 Ethylene Oxide Spill Neutralization

Ethylene oxide spills can be dissolved with lots of cold water. Ethylene oxide vapor clouds can be washed out with water spray. If ethylene oxide is spilled into water in aquatic media, ethylene oxide will degrade by hydrolysis with a half-life of ~12–14 d. Evaporation from aquatic media will also be a significant loss process.

### 1.4.2 Fighting of Ethylene Oxide Fires

Ethylene oxide fires can be extinguished with water, carbon dioxide, or bicarbonate powder fire extinguishers. Water is favorable in that the burning puddle of liquid will soon be diluted below the flash point and will quit burning. A volume of water 22 times the volume of the spilled fuel is needed to dilute the fuel below the flash point. Halon 1301, which is often used for fighting fires in electrical and high-value installations, is not as effective as sodium bicarbonate dry chemical extinguishers, but it is still better than carbon dioxide. Fire-fighting personnel must wear respiratory protection to prevent inhalation of unburnt vapors of EtO.

## 1.5 Safety Properties of Ethylene Oxide

Liquid ethylene oxide is insensitive to initiation by a detonator (blasting cap). Ethylene oxide vapor will detonate when initiated by a detonator, a hot wire, or an electric spark. The limits of flammability in air range from 3 to 100 vol.-% ethylene oxide for upward propagation.

In the absence of air, EtO vapor will decompose exothermally. It has been recommended that EtO containers should be purged with inert gas to prevent the formation of explosive air/EtO mixtures. The inert gas is nitrogen or argon or carbon dioxide.

### 1.5.1 Ignition Energy and Limits of Flammability of Ethylene Oxide in the Absence of Air

Depending on the vessel geometry, the explosive limits in the absence of air will be narrowed by diluent gases. The lower limits of autodecomposition of ethylene oxide initiated by a platinum glow wire in the presence of various diluent gases are summarized in Table 7. The diluent gas should not be very soluble in liquid EtO if the gas is to be used as an inert gas pad on top of the liquid EtO storage container to improve storage safety.

**Table 7:** Lower limits of explosion of ethylene oxide in diluent gases and the solubilities of diluent gases in liquid ethylene oxide.

| Diluent gas    | Limit, vol.-% C <sub>2</sub> H <sub>4</sub> O |                          | Solubility at 202 kPa |
|----------------|-----------------------------------------------|--------------------------|-----------------------|
|                | Lower limit of explosion                      | Upper limit of explosion | Mass%                 |
| Hydrogen       | 25                                            | 100                      | —                     |
| Nitrogen       | 25                                            | 100                      | 0.02                  |
| Carbon dioxide | 18                                            | 100                      | 2.8                   |
| Methane        | 15                                            | 100                      | 0.02                  |

The ignition of EtO decomposition flames in the absence of air was investigated by spark and hot wire ignition techniques [53]. Below a limiting pressure and in narrow tubes, the ethylene oxide decomposition flame fails to propagate. The critical diameter below which the flame extinguishes can be expressed as a function of operating pressure by the following equation:

$$d_q = \frac{10}{p}$$

where  $d_q$  is the critical diameter of extinguishment in mm and  $p$  is the pressure in atm. At atmospheric pressure, the critical diameter is 10 mm. For comparison, the critical diameter of air/methane flames is 1 mm. The minimum spark ignition energy required for EtO decomposition flames is four orders of magnitude higher than that for air/EtO flames. There are several different theoretical methods for predicting the flame speed, flame temperature, and exhaust composition, and some of the results agree quite well with experimental measurements. The theoretical flame temperature is 1600 K. The electrostatic discharge energy required to initiate the monopropellant decomposition of EtO (in the absence of air) is 10000 times greater than the energy required to ignite a stoichiometric air/EtO mix at 1 atm and 298 K.

The explosion limits of EtO/GN<sub>2</sub> mixtures under pressure and preheated to the point of ignition at 723–833 K (450–560 °C) in a pressure bomb were measured as a function of EtO content, temperature, and pressure [54]. The activation energy

was not very dependent on EtO concentration. The induction period was  $< 10$  s and decreased with increasing temperature and EtO content.

When studying the ignition properties of EtO at high pressure, the ignition of EtO was examined near heated vertical surfaces under natural convection conditions, where the materials were heated in excess of the thermodynamic critical pressure [55].

At very high pressures, many materials become detonable that ordinarily are considered safe to handle. Decomposition waves in liquid EtO were investigated both theoretically and experimentally with an emphasis on near-critical conditions, where the liquid surface within the wave approaches its thermodynamic critical point [39]. Wave velocities, temperature distributions, and sample conditions required for ignition were measured for pressures up to 24 MPa. Laminar waves were observed for pressures of 6–16 MPa, and turbulent waves were observed at higher pressures. In the laminar regime, wave velocity was a linear function of pressure, indicating a global second-order reaction. Heated or fused wires were used as ignitors since ignition energies were in excess of 8 J. Under subcritical conditions, film boiling occurred along the wires prior to ignition. Measurements confirmed predictions that critical combustion occurs at pressures of 12–16 MPa.

In an effort to obtain data on explosive limits for EtO/nitrogen explosions beyond the published data range, additional tests were conducted at temperatures from 333 to 463 K (60–190 °C) and pressures in the range 69–551 kPa (10–80 psig) [56]. Initial measurements showed that the limits for the EtO/GN<sub>2</sub> system are very dependent on the type of ignition source. Hot wire ignition gave very erratic responses. Induction coil sparks were not satisfactory due to inadequate energy and uncertain gap breakdown at elevated pressure. High-energy capacitive discharges across an exploding bridge element gave responses that were reproducible and judged to be true and conservative. A graphite fiber was used as the exploding bridge “wire” to avoid metal contamination of the test mixture. Metals are catalysts, but carbon is a product of EtO decomposition anyway. The data showed that the EtO explosive range becomes wider with increasing pressure at the low end of the temperature range. At modest pressures, the directly measured limits at elevated temperature agreed with extrapolations of earlier reported data.

A mathematical equation was developed that expressed the decomposition explosion limits applicable to liquid ethylene oxide storage conditions [57]. This equation can be used to maintain safe operating limits of EtO storage tanks.

An experimental and theoretical investigation of explosive decomposition of EtO at fixed initial experimental parameters ( $T = 373$  K = 100 °C,  $P = 400$  kPa = 4 bar) in a 20-L sphere measured safety-related parameters, namely the maximum explosion pressure, the maximum rate of pressure rise, ignition energy, and the  $K_d$  values for pure EtO and EtO diluted with GN<sub>2</sub> [58]. All these dependencies were quantified in empirical formulas. Additionally, the effect of turbulence on explosive decomposition of EtO was investigated. In contrast to previous studies, it was found that turbulence significantly influences the explosion severity parameters, mostly the rate of pressure

rise. Thermodynamic models were used to calculate the maximum explosion pressures of pure and of nitrogen-diluted EtO at different initial temperatures. There was a relation between the amount of soot formed and the explosion pressure.

Explosive limits of the decomposition reactions of mixtures of ethylene oxide, propylene oxide, and nitrogen at temperatures from 373 to 473 K (100–200 °C) and pressures from 100 to 600 kPa (1.0–6.0 bar) were determined by experiment [59]. A comparison with literature data indicated that the results are also applicable to larger vessels and ignition sources with intermediate energy.

Gas phases of EtO and propylene oxide, commonly used for large-scale industrial alkoxylation reactions, can decompose explosively with enormous temperature and pressure rises, even without the presence of air. To estimate the consequences of such runaway reactions, explosion peak pressures and rates of pressure rise of EtO and certain mixtures of EtO and propylene oxide at temperatures between 373 and 473 K (100–200 °C) and pressures between 100 and 1000 kPa (1–10 bar) were determined experimentally using vessels with volumes of 3 L (3 dm<sup>3</sup>) and 100 L (100 dm<sup>3</sup>) [60]. See also [61].

Carbon dioxide is most frequently used to inert ethylene oxide and ethylene oxide/air mixtures, but large amounts of carbon dioxide are required to render such gas mixtures non-flammable and non-detonable. The limits of flammability of the ternary system air/ethylene oxide/carbon dioxide were determined by experiment [62].

### 1.5.2 Autoignition Temperature of Ethylene Oxide in Air

The very low ignition energy of EtO in air makes mixtures prone to electrostatic discharge ignition. Its large burning velocity and flammable range make flame acceleration likely under conditions of confinement or in the presence of obstacles. Acceleration is not seen in free-air deflagration. The autoignition temperature (AIT) depends on the vessel volume and surfaces. Using the ASTM method, EtO has an AIT of 718 K (445 °C). Acetaldehyde, an isomer of EtO, has an AIT of 468 K (195 °C). The presence of acetaldehyde is important for lowering the ignition temperature. Acetaldehyde may be catalytically produced by isomerization from EtO on surfaces. Rust may form hotspots for ignition.

### 1.5.3 Explosive Limits of Ethylene Oxide Decomposition in the Absence of Air

The explosive decomposition of EtO when ignited by a melting, exploding 31-gauge Nichrome wire was studied as a function of the diluent gas and pressure [63]. The cylindrical stainless steel explosion vessel used in this investigation had an internal diameter of 11.4 cm (4.5 in.) and an internal volume of 2.44 L (148.9 in.<sup>3</sup>). It was designed for a maximum dynamic pressure of 10.34 MPa (1500 psig). The use of an inert gas to maintain a non-explosive vapor-phase mixture is the only reliable method of preventing an EtO explosion from ignition sources within a vessel. Although propane and butane were most effective in suppressing the explosive decomposition of EtO,

in practice their use is restricted because of their solubility in liquid EtO. The proportion of nitrogen needed to suppress the explosibility of EtO at a partial pressure of 827 kPa (120 psia) and 398 K (125 °C) is 65 vol.-%. However, a small amount of oxygen or an increase in the partial pressure of EtO vapor will raise this figure; hence, in practice it might be necessary to increase the proportion of nitrogen to ~75 vol-% N<sub>2</sub> to cover these contingencies. This procedure necessitates designing a vessel to withstand a working pressure about four times the initial partial pressure of the EtO vapor. Ammonia, steam, propylene oxide, carbon dioxide, and methanol were also tested as explosion suppressants [64].

The boundaries for explosive decomposition of EtO and EtO/GN<sub>2</sub> mixtures in a cylindrical 1.4-L pressure bomb were determined as a function of pressure, temperature, and vapor composition [65]. See also [66–68].

Some studies have indicated that ethylene oxide explosions may propagate through vapor/liquid mixtures. The thermal decomposition limits, autoignition temperatures, and minimum ignition energies of liquid and gaseous EtO were measured under a variety of realistic conditions in equipment simulating pipes in a chemical factory subjected to heating by external fires [69, 70]. This was the most comprehensive examination of conditions leading to EtO accidents. It was shown that flame propagation through liquid-filled lines may occur via decomposition of vapor pockets. The following was concluded as the result of a very detailed experimental test program. In the case of EtO vapor deflagration, the deflagration produces a maximum pressure ratio of about 12:1. The pressure ratio decreases with increased initial temperature and surface-to-volume ratio of the container. It increases with increased initial pressure. The pressure ratio can be greatly increased in the presence of EtO mist or spray. A flame above condensed liquid may cause some liquid decomposition. At certain elevated temperature and pressure combinations, the flame will propagate directly into the liquid phase (!). Tubular bundle flame arrestors can be effective in quenching decomposition flames. In the absence of air, EtO has a relatively high autodecomposition temperature (ADT) of about 723 K (450 °C) in small equipment such as pipes with diameters of less than 4 in. High nitrogen dilution has little effect on the ADT. However, proper inerting will prevent flame propagation from the initiation site. Decomposition is difficult to initiate from point sources under normal storage or handling conditions. EtO is not prone to static ignition or steel–steel impact sparks of short duration. Decomposition may be initiated by reactive hotspots such as rust at temperatures well below the ADT. The mechanism may involve either polymerization or isomerization. For EtO liquid deflagration, point source ignition requires severe temperature and pressure combinations. Under fire exposure conditions, establishment of a vapor decomposition zone in a pipeline may allow flame propagation in a liquid-filled line. If a high pressure is generated, then a transition to a true liquid decomposition may occur. Based on tests in an accelerating rate calorimeter in a titanium bomblet, pure EtO requires about 473 K (200 °C) to initiate a runaway reaction under adiabatic conditions. The reaction

involves isomerization and aldol condensation reactions. The runaway reaction threshold temperature is greatly reduced by water and miscellaneous initiators. Solid catalysts that facilitate ignition include iron oxide, aluminum oxide, and various types of insulation, particularly asbestos and calcium silicates.

Undiluted EtO vapor may propagate decomposition flames through a pipe above certain minimum conditions of temperature, pressure, and pipe diameter. Flame propagation was studied in both closed and vented 5-cm (2-in.) diameter pipe and closed 30-cm (12-in.) diameter pipe [71]. Flame progression in a closed pipe was irregular and proceeded in pulsed stages. A possible mechanism involves preferential flame propagation at the pipe roof accompanied by periodic autodecomposition of EtO that accumulates in hot products behind the flame front, with the accumulation probably augmented by liquid EtO that has condensed on the pipe walls ahead of the expanding flame system. Flames propagated 15 m (50 ft) through a horizontal 5-cm pipe at 323 K (70 °C) and at initial pressures  $\geq 4.3$  bar (62 psia). In a series of 30-cm pipe tests employing low-energy ignition and otherwise increasingly severe conditions, a deflagration-to-detonation transition (DDT) occurred, partially destroying the test equipment. Two EtO detonations at 2.9 bar and one at 3.5 bar were directly initiated via strong shocks from hydrogen–oxygen detonations used as a donor section.

#### 1.5.4 Adiabatic Compression Sensitivity of Liquid Ethylene Oxide

Whereas other organic monopropellants, e.g., propyl nitrate or acetylene, are susceptible to detonation initiated by adiabatic compression or local cavitation in turbulent flow at sharp corners, liquid EtO is stable even if rapidly compressed at 1362 atm/s (20000 psi/s) or in turbulent flow in sharp-edged orifices [72]. Even in the presence of small inert gas bubbles, it cannot be initiated by adiabatic compression. The sample holder cell had a diameter of 12.2 mm and held 2 mL of sample liquid.

When tested in stainless steel tubes with 63 mm (2.5 in.) O.D., 13.3 mm (0.52 in.) wall thickness, and 16.5 cm (6.5 in.) length with a 100-g tetryl charge as the donor, liquid ethylene oxide at 276 K (3 °C) was partially detonable (incomplete propagation), and it was suspected that at higher temperatures the detonation might have propagated the entire length of the tube [73].

#### 1.5.5 Adiabatic Compression Sensitivity of Ethylene Oxide Vapor

Conditions leading to spontaneous ignition of ethylene oxide vapor were explored in circumstances where the vapor was subjected to rapid compression and heating due to adiabatic compression [74]. Experiments were carried out using a rapid compression apparatus on dilute mixtures of ethylene oxide in argon, and on systems containing varying amounts of added oxygen. The total initial pressure was varied from 13 to 50 kPa and the compression ratio from ca. 10:1 to ca. 12:1. Pressure–time histories were measured, and gas temperatures were derived from them. Emitted light intensities were recorded and overall compositions were measured by mass spectrom-

etry. Decomposition occurred rapidly at temperatures of about 850 K and the exothermicity exceeded 100 kJ/mol. Ignition of ethylene oxide was possible in the mixture of  $1\text{C}_2\text{H}_4\text{O} + 20\text{Ar}$  when compression was more than 11-fold. A typical ignition delay was 5 ms. Trace amounts of added oxygen enhanced the reaction rate and the extent of self-heating. With roughly equal amounts of ethylene oxide and oxygen, ignition occurred in circumstances where none would be possible in the absence of oxygen, and the delay was very short ( $< 2$  ms). The results showed that small amounts of ethylene oxide ( $< 1$  vol-%) in air are a potential explosion hazard if modest but rapid compression occurs.

Compressing ethylene oxide vapor mechanically by a mechanical piston apparatus is a slow process compared to compression of ethylene oxide vapor in a shock tube. Shock tube compression is a useful method to measure decomposition kinetics because the temperature can be increased quickly to a pre-set value. The decay of the reactants is then measured spectroscopically. The pyrolysis of ethylene oxide highly diluted in argon was studied behind reflected shocks in a single-pulse shock tube at 830–1200 K, and total pressures behind the shocks varied between 1.5 and 10 atm [75]. The rate of production of the various reaction products varied by up to four orders of magnitude over this temperature range. The concentrations of  $\text{C}_2\text{H}_6$ ,  $\text{CH}_4$ ,  $\text{C}_2\text{H}_2$ ,  $\text{C}_3\text{H}_8$ ,  $\text{CH}_3\text{CHO}$ , and  $\text{H}_2$  were determined as a function of temperature, total density, and initial ethylene oxide concentration. It was shown that the main channel for pyrolysis is ethylene oxide–acetaldehyde isomerization, yielding methyl and formyl radicals as well as methane and carbon monoxide upon decomposition. The formation of ethylene and acetylene could not be explained on the basis of the isomerization channel. Rupture of the C–O bond in ethylene oxide by H-atom substitution was suggested to account for the production of these products.

Ignition delay times in ethylene oxide/oxygen/argon mixtures behind a reflected shock were measured in a 24.3-mm diameter shock tube [76]. The shock-tube driver section gas was pure helium. Nine different test gas mixtures with various concentrations of argon were prepared so that its effect on the reaction rate of the ignition could be evaluated. In all of the experimental runs, the initial pressure of the test mixture in the driven section was 13.3 kPa (100 mm Hg), except for mixtures with high concentrations of EtO, where the initial pressure was fixed at 7.5 kPa (56 mm Hg).

## 1.6 Accident History of Ethylene Oxide

Numerous accidents have occurred during the use of EtO. The chemical industry and their insurance companies have combined their efforts to prevent future accidents of this type [77].

The occasional occurrence of EtO explosions during the fumigation of dried fruit led to detailed studies of the combustion characteristics of the vapor [78]. The spontaneous ignition temperature is similar to that of acetaldehyde. Cool flames can be ini-

tiated in air/EtO mixtures in the neighborhood of 603 K (330 °C) at atmospheric pressure.

In the literature there are many more descriptions of industrial accidents with ethylene oxide [79]. The most serious accident, which occurred on 24 June 1997 at Accra Pac, an ethylene oxide re-packager in Elkhart, IN, killed one worker and injured 69 others.

Ethylene oxide is widely used as a sterilizing agent for medical and food applications and products. However, due to its broad range of flammability in air, this gas presents a particularly serious explosion hazard, which is compounded by extremely stringent and ever-increasing requirements for pollution control equipment. Many pollution control devices contain potential ignition sources, such as open flames or hot catalysts, that could trigger an explosion. An explosion that caused extensive damage at a sterilization facility in the United States in August 2004 occurred as workers were attempting to troubleshoot one of their sterilization chambers and consequently bypassed safety interlocks while evacuating the gas [80, 81]. This allowed a flammable mixture to enter an ethylene oxide incineration unit that utilized an open flame to pre-heat waste gases before they passed through a catalytic oxidizer bed. The resulting deflagration propagated through the ductwork and back into the sterilization chamber, which exploded. Alert notices and safeguard instructions have been issued to prevent any further accidents of this type [82].

## 1.7 Toxicity of Ethylene Oxide

At low concentrations, the odor of ethylene oxide is similar to that of ether, but at higher concentrations it will irritate the mucous membranes and the respiratory tract [51]. The threshold for the onset of irritation is 50 ppm by volume (90 mg/m<sup>3</sup>).

Long-term inhalation of EtO below the irritation threshold causes headache, nausea, and vomiting. Generally, these symptoms subside within 24–36 h after the victim is moved to fresh air. The sensitivity of victims to renewed exposure is increased in the case of recurring exposure to vapors of this propellant. Repeated exposure to lower concentrations can cause chronic respiratory irritation, anemia, and some damage to the liver and kidneys. Inhaled ethylene oxide induced pre-neoplastic foci in rat liver [83].

In acute studies in laboratory animals, the LC<sub>50</sub> values for inhalation exposure (rats, mice, and dogs) ranged from 835 to 5000 ppm for a 4-h exposure, and the oral LD<sub>50</sub> value (rabbits, guinea pigs, and rats) ranged from 100 to 631 mg/kg body weight.

Inhalation of 5–10 vol.-% EtO in air was fatal to guinea pigs within a few minutes. Liquid EtO spilled on skin can cause serious skin burns if the chemical is not immediately washed off with lots of water. Aqueous solutions of EtO are highly irritating to the skin and may sensitize it to future exposures.

### 1.7.1 Ethylene Oxide Permissible Exposure Limits in Air

Conversion factor: 1 ppm = 1.80 mg/m<sup>3</sup> at 25 °C and 1 atm.

NIOSH IDLH: 800 ppm

OSHA PEL: 1 ppm/5 ppm (15 min excursion)

TWA, cancer hazard, suspected human carcinogen [84]

NIOSH REL: 0.1 ppm = 0.18 mg/m<sup>3</sup>

TWA: 5 ppm = 9 mg/m<sup>3</sup> (<10 min/day) ceiling concentration

Potential carcinogen. Limit exposure to lowest feasible level, see *NIOSH Pocket Guide*, Appendix A [85].

ACGIH TLV: 1 ppm = 1.8 mg/m<sup>3</sup>

Protective Action Criteria (PAC)

TEEL-0: 1 ppm

PAC-1: 5 ppm

PAC-2: 45 ppm

PAC-3: 200 ppm

The chosen IDLH of 800 ppm was based on the observation that the estimated LC50 for a 4-h exposure was approximately 800–1500 ppm, depending on the species. It was stated that for humans, 500 ppm is probably safe for single exposures (no more than once per week) of 1 h duration [86, 87].

### 1.7.2 Harmful Effects and Symptoms of Ethylene Oxide Exposure

**Short-Term Inhalation Exposure:** Signs and symptoms of acute exposure to ethylene oxide may be severe and include dyspnea (shortness of breath), cough, pulmonary edema, pneumonia, and respiratory failure. Lethargy, headache, dizziness, twitching, convulsions, paralysis, and coma may be observed. Cardiac arrhythmias and cardiovascular collapse may also occur. Gastrointestinal effects of acute exposure may include nausea, vomiting, and abdominal pain. Ethylene oxide irritates the eyes, skin, and respiratory tract. Very high exposures can cause pulmonary edema, a medical emergency that can remain unrecognized for several hours.

**Inhalation:** Acute exposure to EtO gas may result in respiratory irritation and lung injury, headache, nausea, vomiting, diarrhea, shortness of breath, and cyanosis. Chronic exposure has been associated with the occurrence of cancer, reproductive effects, mutagenic changes, neurotoxicity, and sensitization. Exposure to 500–700 ppm for 2–3 min resulted in nausea, vomiting, headache, disorientation, fluid in the lungs, followed by seizures. Human volunteers breathing a concentration of about 2500 ppm experienced slight irritation of the respiratory tract; breathing in 12500 ppm led to definite respiratory tract irritation within 10 s. Symptoms may not occur for hours after exposure.

**Skin:** The pure liquid may cause frostbite. A 1% water solution can cause irritation and redness. A 40–80% water solution may cause extensive blister formation. Ethylene oxide may severely irritate or burn mucous membranes and moist skin.

**Eyes:** May cause irritation and severe burns. May affect the eyes, causing delayed development of cataract. Eye contact may result in conjunctivitis (red, inflamed eyes) and erosion of the cornea.

**Ingestion:** May cause gastric irritation and liver injury.

**Long-Term Exposure:** Repeated or prolonged contact with skin may cause a skin allergy. EtO may affect the nervous system, kidneys, adrenal glands, skeletal muscles, and cause reproductive effects. It may be carcinogenic to humans. Exposure to low concentrations of gaseous EtO may cause irritation to the respiratory tract and eyes, loss of sense of smell, and nausea and vomiting. Repeated skin exposure can cause scaling, cracking, and redness. Exposure to 5–10 ppm for 11 years or to 1 ppm for 15 years has caused blood changes. EtO has caused cancer in several species of laboratory animals. It has also caused changes in genetic material and reproductive problems in laboratory animals. EtO may damage the developing fetus. It may cause inheritable genetic damage in humans. There is an increased incidence of gynecological disorders and spontaneous abortions among workers in ethylene oxide production.

Case reports of workers exposed repeatedly to ethylene oxide indicated the occurrence of neurotoxicity consistent with sensorimotor neuropathy. Some signs of neuropathy appeared to persist even after cessation of exposure. In occupational epidemiology studies, the non-neoplastic results were reported to be an increase in lymphocyte count, a decrease in hemoglobin value (levels of exposure were not reported), and an increased incidence of deaths resulting from diseases of the circulatory system (exposure level < 50 mg/m<sup>3</sup>).

Ethylene oxide has been shown to induce gene mutations in bacteria, fungi, higher plants, *Drosophila*, and cultured mammalian cells in tests conducted without the use of exogenous hepatic metabolic activation systems. On the basis of the human, animal, and mutagenic data, ethylene oxide is classified as being “probably carcinogenic to humans” and belonging in EPA Group B1. See also [88–90].

## 1.8 Other Applications of Ethylene Oxide

Ethylene oxide is used in the synthesis of hydroxyethylamines and hydroxyethylhydrazine by reaction with ammonia or hydrazine. Trihydroxyethylammonium nitrate (TEAN) was used as a fuel in liquid gun propellants LP-1845 and LP-1846. It is a candidate fuel for hydroxylammonium nitrate-derived monopropellants in rockets, as is hydroxyethylhydrazinium nitrate, which can be made from ethylene oxide and hydrazine hydrate and is used in AF-M315E.

Ethylene oxide is widely used for the sterilization of surgical equipment. Unfortunately, several explosions have occurred in sterilization facilities because the hazardous properties of EtO were not totally understood or the facility was not operated correctly.

For many years, ethylene oxide diluted with carbon dioxide (Oardox) was used for killing insects in grain silos. At the concentrations used, it was also toxic to rats and mice. Per 10CFR § 185, the FDA has only approved ethylene oxide fumigation for raw spices, dehydrated vegetables, and spice blends that do not contain salt.

## 2 Propylene Oxide

Propylene oxide, also known as 1,2-propylene oxide, 2-methyloxirane, 1,2-epoxypropane,  $C_3H_6O$ , CAS RN [75-56-9],  $MW = 58.079$  g/mol, is a homologue of ethylene oxide with similar chemical properties. The oxirane ring adds energy to the propane molecule.

Propylene oxide

A good overview of the production and industrial uses of propylene glycol is published in the encyclopedic literature [91]. Propylene oxide may be co-polymerized with ethylene oxide or tetrahydrofuran to form polyether polymers that are useful as binders in solid propellants. Polyol pre-polymers may consist of propylene oxide oligomers with only a dozen ether linkages. In the chemical industry, most propylene oxide is hydrolyzed to propylene glycol, which is used as an antifreeze and as the starting product for synthesis of propylene glycol dinitrate (see the chapter “Nitrate Esters” in *Encyclopedia of Oxidizers*). It can also be converted to glycerol. Propylene oxide can be reacted with cellulose to make hydroxypropylcellulose. Hydroxypropylcellulose is a gelling agent for hydrazine, MMH, and other hypergolic fuels.

Propylene oxide is the parent compound for glycidyl azide, which, in the polymerized form, is a high-energy binder for solid propellants. Propylene oxide is more thermally stable than ethylene oxide [92].

Because of their reliable ignition and instant detonation, air/propylene oxide mixtures have been used in the donor section of a shock tube for studying DDT detonation transitions in air/isopropyl nitrate mixtures [85].

Propylene oxide is used in fuel-air explosive (FAE) bombs. The flammable range of propylene oxide in air is 2.8–37 vol.-%. Other sources have reported a flammable range of 2.3–36 vol.-% in air. There is no MIL SPEC for propylene oxide. Propylene oxide

could be used as a fuel for bipropellant, pulsed detonation, or rotating detonation engines. Although the combustion [93] and detonation [94] of oxygen/propylene oxide mixtures have been studied, there are no indications that such mixtures have already been used in rocket engines.

As far as the toxicity of propylene oxide is concerned, the OSHA PEL TWA is 100 ppm, and the original NIOSH IDLH of 2000 ppm was lowered to 400 ppm. The reported dog 4-h LC<sub>50</sub> was 2005 ppm and the mouse 4-h LC<sub>50</sub> was 1740 ppm, as cited by NIOSH [87].

### 3 Oxetane Derivatives

Oxacyclobutane, oxetane, is a cyclic ether and is the parent for a number of derivatives of interest as rocket propellant ingredients. Oxetanes are four-membered rings containing one oxygen atom. The simplest oxetane is 1-oxacyclobutane. The energetic groups are usually attached at the 3-position of the oxetane ring. One or two groups can replace the hydrogen(s) at the 3-position. The energetic binders derived from azido oxetane derivatives are called azidated oxetanic polymers.

Oxetane and its derivatives can be polymerized to form polyethers. Lewis acids act as catalysts for this ring-opening reaction. Widely used energetic polymers are formed from 3-nitratomethyl-3-methyloxetane (polyNiMMO), 3,3-bis(azidomethyl) oxetane (BAMO), and azidomethyl methyloxetane (polyAMMO). There will be several sections on these energetic polymeric binders in planned future volumes on solid propellants in the *Encyclopedia of Rocket Propellants*. Energetic polyoxetanes based on BAMO and AMMO were discovered in 1982 [95].

#### 3.1 Nitrooxetanes

3-Nitrooxetane was made by oxidation of 3-aminooxetane. It boils at 350 K (77 °C) at reduced pressures of 0.5–1.0 mm Hg. 3,3-Dinitrooxetane can be made by reaction of the sodium salt of 3-nitrooxetane with silver nitrate or by nitration with tetranitromethane [96]. 3,3-Dinitrooxetane melts at 343–344 K (70–71 °C).

#### 3.2 Azidooxetanes

3-Azidooxetane (AZOX) can be made by reaction of 3-oxetyl tosylate with sodium azide [96]. Distillation of 3-azidooxetane begins at 363 K (90 °C). The polymerization of 3-azidooxetane has given potentially useful difunctional oligomers.

## 4 Other Ethers

### 4.1 Vinyl Alkyl Ethers

Vinyl isobutyl ether, and vinyl ethyl ether, also known by the code name Visol, were used in Germany during WWII as hypergolic fuels with WFNA or RFNA in the WASSERFALL and TAIFUN anti-aircraft missiles. The radar-guided WASSERFALL was a precursor to the American NIKE anti-aircraft missile. HERMES, one of the first liquid-propelled missiles developed by the US Army after WWII, had a striking external similarity to the WASSERFALL. It is unlikely that vinyl ethers will ever again be used as hypergolic fuels, but, in order to provide a complete history of rocket propellants, the production and physical properties of vinyl ethers are discussed here.

#### 4.1.1 Production of Vinyl Alkyl Ethers

Vinyl alkyl ethers can be made from acetylene and alkanols by the Reppe synthesis [97]. Visol-1 (isobutylvinyl ether) and Visol-4 (butanediol-1,4-divinyl ether) were prepared from alcohols and diols via the Reppe technique by reaction with acetylene under high pressure:

The acetylene has to be diluted with nitrogen to prevent explosions at high pressures [98, 99]. Various types of alkyl vinyl ethers can be synthesized by the reaction of alcohols with vinyl acetate under the influence of a catalytic amount of an iridium catalyst combined with  $\text{Na}_2\text{CO}_3$  [100].

#### 4.1.2 Properties of Vinyl Alkyl Ethers

Table 8 shows the properties of two vinyl alkyl ethers that have been used as rocket propellants. Vinyl ethers can be stored at room temperature for only a few months, even when water and acids are carefully excluded. *N,N*-Diethylaniline can be added as a stabilizer.

#### 4.1.3 Applications of Vinyl Alkyl Ethers

Vinyl ethers were used as rocket fuels in Germany during the years 1940–1945. The code name Visol-1 was given to *n*-butylvinyl ether (b.p. at 750 mm Hg: 355 K = 82°C), the code name Visol-2 or -3 was given to isobutylvinyl ether, and the code name Visol-4 was given to butanediol-1,4-divinyl ether (b.p. at 20 mm Hg: 333–338 K =

**Table 8:** Properties of vinyl alkyl ethers.

| Property                                         | Ethyl vinyl ether                                     | Isobutyl vinyl ether                                    |
|--------------------------------------------------|-------------------------------------------------------|---------------------------------------------------------|
| Formula                                          | $\text{C}_2\text{H}_5-\text{O}-\text{CH}=\text{CH}_2$ | $\text{i-C}_4\text{H}_9-\text{O}-\text{CH}=\text{CH}_2$ |
| CAS RN                                           | [109-92-2]                                            | [109-53-5]                                              |
| Freezing point                                   | 158 K = $-115^\circ\text{C}$                          | 161 K = $-112^\circ\text{C}$                            |
| Boiling point                                    | 309 K = $36^\circ\text{C}$                            | 356 K = $83^\circ\text{C}$                              |
| Density at $20^\circ\text{C}$                    | 0.754 g/cm <sup>3</sup>                               | 0.769 g/cm <sup>3</sup>                                 |
| Refractive index ( $n_D^{20}$ )                  | 1.3767                                                | 1.3965                                                  |

Data source: [97]

60–65°C) [101]. Visol-6 was the code name for vinyl ethyl ether. Visols are hypergolic with WFNA and burn softly (no chamber pressure oscillations), similar to turpentine. They can also be mixed with amines to obtain shorter ignition delays.

Visol-1 was used with WFNA in the German WASSERFALL anti-aircraft rocket during WWII. Isobutylvinylether has a boiling point of 355 K ( $82^\circ\text{C}$ ) at 750 mm Hg, and butanediol-1,4-divinyl ether has a boiling point of 333–338 K = 60–65°C at 20 mm Hg. The Visol that was used in the small TAIFUN rocket was incorrectly described as a “mixture of hydrocarbons” [102].

## 4.2 Triethylene Glycol Dimethyl Ether

The Gelled Propellants Laboratory at Purdue University has tested the ignition of HTP with  $\text{NaBH}_4$ /triglyme (triethylene glycol dimethyl ether) as fuel, so one can assume that  $\text{NaBH}_4$ /triglyme is one of the fuel A or fuel B combinations quoted by other Purdue researchers [103].

Triglyme, triethylene glycol dimethyl ether,  $\text{C}_8\text{H}_{18}\text{O}_4$ , 2,5,8,11-tetraoxadodecane, 1,2-bis(2-methoxyethoxy)ethane, dimethyltriglycol, CAS RN [112-49-2], is a clear liquid with a density of 0.986 g/cm<sup>3</sup>, a freezing point of 227 K ( $-46^\circ\text{C}$  =  $-51^\circ\text{F}$ ), and a boiling point of 489 K ( $216^\circ\text{C}$  =  $421^\circ\text{F}$ ) at atmospheric pressure.

## 4.3 Methyl *tert*-Butyl Ether

In the 1990 Clean Air Act Amendments, Congress mandated the addition of oxygenated fuels to gasoline to reduce toxic emissions and improve air quality in urban areas. Besides ethanol, the main oxygenated fuel additive was methyl *tert*-butyl ether, which has the advantage that it also improves the octane rating of gasoline and can be made in refineries instead of corn fermentation plants. Methanol and

isobutylene can be reacted over catalysts to produce methyl *tert*-butyl ether, MTBE. MTBE was used as a gasoline additive (anti-knock enhancer) but ended up polluting the groundwater. MTBE was introduced to reduce air pollution, but its use has created another environmental problem: contamination of groundwater and drinking water wells. Many states have banned the use of MTBE in gasoline, pointing out that the same reduction in automobile emissions can be achieved with ethanol as the oxygenate. Because MTBE is readily available, and because it is a good solvent for hypergolizing additives, it could be used as a rocket fuel.

# Heterocyclic and Heterocycloaliphatic Amines

## Introduction

*Encyclopedia of Liquid Fuels* contains three chapters on amines: “Aliphatic Amines,” “Aromatic Amines,” and “Heterocyclic and Heterocycloaliphatic Amines.” The current chapter on Heterocyclic and Heterocycloaliphatic Amines is the largest of the three. Amines are used as rocket fuels and as raw materials for the synthesis of other fuels and energetic compounds. A different type of amine are the nitramines described in the chapter “Nitramines.”

## 1 Heterocyclic and Heterocycloaliphatic Amines

There are several reasons behind the widespread interest in the diverse chemistry of heterocyclic compounds, with focus especially being on potential rocket propellants, gas generants, and explosive applications. Initially, the interest lay mostly in high-nitrogen compounds for gas generants such as that in airbag inflators, with 5-aminotetrazole being the leading candidate in this application.. The search for less sensitive replacements for 1,3,5-trinitro-1,3,5-hexahydrotriazine (RDX) and 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX) (themselves heterocyclic compounds) has driven many investigations into other nitrogen-containing ring systems. Many of the **High-Energy-Density Material** (HEDM) compounds listed in this chapter on heterocyclic compounds predominantly behave as explosives. Nonetheless, they are listed in this book on rocket propellants because, while they are detonable in their pure state, they can be incorporated in rocket propellant formulations similar to nitramine propellant formulations based on RDX. RDX is an explosive but many nitramine solid propellants safely incorporate a limited amount of RDX in their formulations. A similar approach is possible by using many of the energetic compounds described in this chapter in place of, or in addition to, RDX.

If the title of this book could be expanded, it would read “Encyclopedia of Liquid Fuels, Rocket Propellants, and Other Energetic Materials” since much of the information on other energetic materials is provided in this chapter. Although most of the HEDM energetic materials that will be discussed do not qualify as rocket propellants, we have attempted to include them here nevertheless to demonstrate the relationships between chemical structures, energy content, and sensitivity. The boundaries between a less sensitive and poor explosive and an excessively sensitive but overly energetic rocket propellant are not well defined. Many rocket propellant chemists, in the search for more energetic rocket propellants, unwittingly ended up with an explosive instead. We therefore will venture into this area, always keeping safety in mind.

Of the hundreds of chemical compounds listed in this chapter, only very few will ever advance to the level of industrial production and widespread applications in rocket propellants. The process of developing, characterizing, and eventually selecting a few outstanding performers in this group of chemicals for rocket propellant applications has kept chemists busy for half a century and promises to do so for a few more years to come.

Most of the compounds described in this chapter are solids; this chapter, therefore, is rather misplaced where it is currently located (in *Encyclopedia of Liquid Fuels*). However, as most heterocyclic energetic compounds do not qualify as solid binders for solid propellants, they would be misplaced within a volume on solid propellant binders (fuels) too.

The parent compounds of families of energetic materials (the heterocyclic amines described at the entrance of each section) are not used as rocket propellants as such. They only serve as the skeleton to which functional groups are attached in an effort to obtain energetic materials or ionic liquids suitable as rocket propellants.

Only during the past 25 years has the search for ionic liquids added a new twist to heterocyclic chemistry. Ionic liquids (ILs) can be used as monopropellants by themselves, as fuels for monopropellants with other oxidizers (e.g., hydroxylammonium nitrate, HAN) and as fuels for hypergolic bipropellant combinations in an effort to find a non-volatile replacement for methylhydrazine (MMH). A separate chapter describes the chemistry and applications of ionic liquids (*Encyclopedia of Liquid Fuels*, “Ionic Liquids” chapter), although there is some overlap between the former and the chapter at hand.

While much work with solid heterocyclic compounds was directed at less sensitive, thermally more stable energetic materials, other efforts aimed in the opposite direction, looking for replacements for lead azide as a primer explosive. The first stab-sensitive heterocyclic compound in this category was tetrazene (tetracene), however, several other primary explosive compounds have been discovered since then, including some in the form of metal (non-toxic, non-lead) salts of heterocyclic compounds. These can serve as non-toxic replacements for lead azide and mercury fulminate.

Although the unsubstituted heterocyclic parent compounds are not very useful as propellant ingredients, we have included them in this book to better understand the effects of substitution on the rings on thermal stability, chemical reactivity, and enthalpy of formation of these molecules. The substituents most often attached to heterocyclic rings are nitro, nitramino, azido, hydrazino, difluoroamino, and amino groups (preferably explosophoric groups). Hopefully, with this fundamental understanding, we are becoming more knowledgeable in this area. Moreover, with continuing advances in computational chemistry, one will be able to create “designer explosives” or “designer energetic materials” as rocket propellant ingredients. It may be as simple as clicking on a computer screen before going to the laboratory and mixing the relevant ingredients in an attempt to accomplish the hands-on synthesis of energetic ingredients.

Heterocyclic compounds with nitro, nitramino, difluoroamino, trinitromethyl, or oxo groups as substituents are candidates for explosives. Other heterocyclic compounds with amino, hydrazino, cyano, azido or alkyl groups are candidates as high-nitrogen compounds and fuels. There are a few good summaries available regarding the use of heterocyclic compounds as propellant ingredients [1–3]. These will need to be updated frequently and continuously to keep up with the progress of developments in this area.

This chapter on heterocyclic amines is one of the most complex in this book due to the inclusion of a very large number of different chemical compounds. It is difficult to organize this amount of information in a systematic manner. While other chapters on energetic compounds in this book were arranged by the increasing number of carbon atoms in the molecule, we chose the total number of atoms in the heterocyclic ring and the increasing number of nitrogen and oxygen heteroatoms as the ordering system for the following sections on heterocyclic compounds. This sorting scheme lists the number of carbon atoms in decreasing order as more and more carbon atoms in the ring structure are replaced by nitrogen (or oxygen in a few cases). The increased nitrogen content makes the compounds more energetic and more suitable as ingredients in gas generants, e.g., in airbag inflator gas generators.

Many heterocyclic compounds occur naturally in alkaloids, medicinal herbs, and amino acids, and coal tar also. Consequently, the main applications of heterocyclic compounds are in pharmaceutical products and in synthetic dyes. Many heterocyclic compounds have aromatic resonance structures similar to benzene. The most common heterocyclic amine is pyridine, often found as a contaminant in benzene derived from coal tar. Heterocycloaliphatic amines do not have resonance structures; they are cycloalkanes, which is when one or more carbon atom has been replaced by nitrogen. They often are obtained via the gentle reduction (without ring splitting) of related heterocyclic compounds, e.g., the reduction of pyridine leads to piperidine = hexahydropyridine.

The chemistry of heterocyclic compounds is already very thoroughly investigated and summarized in a series of encyclopedic books. Current research on heterocyclic compounds is published in several scientific journals and books that are exclusively devoted to this area, e.g., *Journal of Heterocyclic Chemistry* [4], *Advances in Heterocyclic Chemistry* [5], *Chemistry of Heterocyclic Compounds* [6], and *Heterocyclic Communications* [7]. While these traditional sources all provide information about the synthesis, physical, and chemical properties of heterocyclic compounds, they contain little information on the energy content, explosive properties, and sensitivity of these compounds. This is why we have attempted to collect some of the relevant information that would be of interest to a rocket propellant chemist.

High-nitrogen compounds are a sub-class of heterocyclic compounds in general. Most heterocyclic compounds contain nitrogen. There are very few heterocyclic compounds that contain only one heteroelement other than nitrogen. The chemistry of heterocyclic compounds is a domain in its own right, as evident from the existing lit-

erature in this area, which contains a lot of useful information for propellant and gas generant formulators (albeit it is hard to find). The following sources of literature on heterocyclic compounds, in general, are worth reviewing.

*Comprehensive Heterocyclic Chemistry III (CHEC-III)* is a 15-volume reference work that should be treated as the first point of call for all scientists interested in heterocyclic ring systems [8, 9]. Since its publication in 1984, it has become the standard reference point on the subject, indispensable to all serious readers in the interdisciplinary areas where heterocycles are employed. *CHEC-III* builds on and complements the material in *CHEC* and *CHEC-II* and is designed to be used both alone and in conjunction with these two works. Volumes 1 and 2 cover three- and four-membered heterocycles, together with all fused systems containing a three- or four-membered heterocyclic ring. Volume 3 covers five-membered rings with one heteroatom together with their benzo- and other carbocyclic-fused derivatives. Volumes 4, 5, and 6 cover five-membered rings with two heteroatoms, three or more heteroatoms. Volumes 7, 8, and 9 cover six-membered rings with one, two, and more than two heteroatoms, respectively. Volumes 10, 11, and 12 cover systems containing at least two directly fused heterocyclic five- and/or six-membered rings. Volumes 13 and 14 cover seven-membered and larger heterocyclic rings, including all their fused derivatives.

A few excellent summaries of current research on high-nitrogen HEDMs based on heterocyclic ring structures have been published while the work is still actively continuing and more publications continue to appear every month. As such, it is difficult to keep track of all new developments in this area. A summary by Singh et al. contains chapters on triazolium-based, tetrazolium-based, tetrazine-based, azetidinium-based, and imidazolium-based high-nitrogen heterocyclic compounds, and is supported by a long list of 126 relevant literature references [2]. For many of the compounds, the melting points, densities, and enthalpies of formation of their various salts formed with nitric acid, perchloric acid, or dinitramidic acid were tabulated. This is an excellent resource for further in-depth studies on this subject. These types of HEDMs derive their energy from a large number of N—N and C—N bonds and their intrinsic energy content rather than a high heat of combustion. Heterocyclic ring compounds typically have higher heats of formation (HOFs) than their isocyclic (alicyclic, cycloaliphatic) analogs. Many heterocyclic high-nitrogen compounds have a positive enthalpy of formation, which makes them attractive options for the production of explosives and propellants. The reactions of heterocyclic rings containing either ring-bound or attached amino groups with nitric acid, dinitramidic, or perchloric acid form highly energetic salts that can find applications in explosives and rocket propellants. Special interest is devoted to salts in which both the cation and the anion are formed from a high-nitrogen compound. Examples in this category are the azolium azolate salts such as triazolium nitrotetrazolate salts, which sport both high energy and a high nitrogen content [10].

Another summary dealing with furazans, triazoles, triazines, tetrazoles, tetrazines, polycyclic cages, and all-nitrogen compounds is [11]. The favorable

properties and disadvantages of these materials are described and possible solutions for these problems are also provided.

Although much of the information on the use of heterocyclic amines as rocket propellants and explosives deals with the amines in the form of their water-soluble salts, the following chapters contain fundamental information on the parent, unprotonated heterocyclic amines. This information is sometimes needed when calculating the properties of the energetic salts derived from the amines by reacting them with strong acids (for monopropellant applications, preferably oxidizing strong acids). The following information on heterocyclic amines and their salts is subdivided into chapters by the number of members in the core ring, most of them being derived from five-membered rings, and a few being derived from six-membered rings. Single-ring systems are discussed first, followed by multiple ring systems, bridged ring systems, and fused-ring systems.

## 2 Three-Membered Ring Amines

Including one or two nitrogens in highly strained three-membered and four-membered ring amines promised to lead to highly energetic fuels and building blocks for other high-energy compounds. There are three saturated three-membered ring cyclic amines with one, two, or three nitrogen atoms in the ring: ethyleneimine (aziridine, azirine; *1H*-azirine, dihydro-; dihydro-*1H*-azirine; dihydroazirine), diaziridine, and triaziridine.

### 2.1 Ethyleneimine

Aziridines are three-membered organic heterocycles that contain one nitrogen atom in the ring.

All commercially available aziridine derivatives are made from ethyleneimine (aziridine) and propyleneimine (2-methylaziridine). Ethyleneimine, aziridine, C<sub>2</sub>H<sub>5</sub>N<sub>1</sub>,

CAS RN [151-56-4], is a colorless liquid that boils at 328.9 K (55.8°C). Polymers of ethyleneimine are usually available as 50% aqueous solutions. An entire book has been devoted to ethyleneimine and other aziridines [12]. A summary of aziridines, describing their preparation, properties, and applications is available in [13]. Various substituted ethyleneimine derivatives have been evaluated as rocket fuels.

### 2.1.1 Preparation of Ethyleneimine

Ethyleneimine can be produced industrially using the  $\beta$ -chloroethylamine process, the Dow process, the BASF-Wenker process, and the catalytic 2-aminoethanol dehydration process. Aziridines, polyethylenimines, and aziridine-modified polymers are used primarily in the coating, paper, water treatment, textile, and petroleum industries.

Until 1963 ethyleneimine was produced commercially by the reaction of 2-chloroethylamine hydrochloride with sodium hydroxide. Dow Chemical once produced ethyleneimine by a reaction of 1,2-dichloroethane with excess ammonia but stopped production in 1978. Badische Anilin und Soda Fabrik (BASF) produced ethyleneimine by reaction of 2-aminoethanol with sulfuric acid to make 2-aminoethyl hydrogensulfate, which was then cyclicized with aqueous sodium hydroxide to produce ethyleneimine. The most economical process is the catalytic dehydration of aminoethanol.

### 2.1.2 Physical Properties of Ethyleneimine

The physical properties of ethyleneimine are listed in Table 1.

**Table 1:** Physical properties of ethyleneimine.

| Property                                                       | SI Units                       | Non-SI units                      | References |
|----------------------------------------------------------------|--------------------------------|-----------------------------------|------------|
| Molecular mass                                                 | 43.0678 g/mol                  | 23.219 mol/kg                     | [14]       |
| Freezing point                                                 | 199 K                          | -74 °C                            |            |
|                                                                | 195 K                          | -78 °C                            | [14]       |

|                                                                | +91.88 kJ/mol                  | +21.96 kcal/mol                   | [16, 17]   |
|                                                                | +91.90 $\pm$ 0.59 kJ/mol       | +21.96 kcal/mol                   | [14]       |
| Heat of vaporization                                           | 33.83 kJ/mol                   | 8.086 kcal/mol                    | [15]       |
| Heat of combustion                                             | 1591.36 kJ/mol                 | 380.3 kcal/mol                    | [14]       |

Ethylene imine is miscible with water in all ratios. Traces of acidity (e.g., already weak acid such as carbonic acid from the air) will cause it to polymerize quickly. The polymerization reaction is exothermic and can lead to the explosion of the storage vessel (a similar polymerization hazard exists with ethylene oxide). For this reason, ethylene imine is usually stored on alkali metal hydroxides, which act as stabilizers and prevent polymerization.

The infrared (IR) spectrum of aziridine vapor is shown in Figure 1.

**Figure 1:** Infrared spectrum of aziridine vapor. (Reproduced and modified with permission from [18].)

### 2.1.3 Reactions of Ethyleneimine

Aziridines can undergo polymerization reactions, i.e., homopolymerization to form polyethyleneimines, or graft and co-polymerization reactions to give aziridine-modified polymers. Polyfunctional aziridines can be obtained by reaction of ethylenimine and propyleneimine and trifunctional acrylates. Ethylenimine and propyleneimine react with amines in ring-opening reactions and with oxiranes and isocyanates under preservation of the aziridine ring.

Ethylene imine can be polymerized, which forms polyethyleneimine, a long-chain secondary aliphatic polyamine that can form salts with a variety of acids. The perchlorate salt of polyethyleneimine is of interest as a coating for AP and other oxidizers. Commercial ethyleneimine usually contains inhibitors to prevent polymerization.

It may be possible to attach fluorine atoms to diazirine  $F_2CN=N$  rings. The cyclic structure of  $F_2CN_2$  has been confirmed by electron diffraction of the vapor [19]. Perfluorodiazirine has  $C_2$  symmetry (planes of  $CF_2$  and  $CN_2$  are mutually perpendicular) with  $C-F = 1.315 \pm 0.004 \text{ \AA}$ ,  $C-N = 1.426 \pm 0.004 \text{ \AA}$ ,  $N=N = 1.293 \pm 0.009 \text{ \AA}$ ,  $\angle FCF = 111.84 \pm 0.52^\circ$ , and  $\angle NCN = 53.95 \pm 0.36^\circ$ . A comparison of the metrics of perfluorodiazirine with  $H_2$  diazirine showed that the  $C-N$  distance was shorter, and the  $N=N$  distance was longer in the former than in the latter by about  $0.06 \text{ \AA}$ .

In air, the flammability limits are: Upper Flammability Limit (UFL): 54.8 vol.-%, Lower Flammability Limit (LFL): 3.3 vol.-%. The flash point (closed cup) is at 262K ( $-11^\circ\text{C}$ ).

Various substituted ethyleneimine derivatives have been evaluated as rocket fuels. The reaction of cyanogen azide with ethylene at 273–303 K (0–30 °C) gives mixtures containing *N*-cyanoaziridine [20].

Ethyleneimine mixtures with ammonia, ethanol, diethylamine, aniline, or hydrocarbons have been patented as hypergolic fuels [16, 17, 21]. It was claimed that adding five to 50 mass-% ethyleneimine to hydrocarbons, alcohols, other amines, ammonia, alkyl hydrazines, hydrazine, and ethers can improve the specific impulse of these fuels.

A mixture of ethylene imine with pyrrole was patented as hypergolic fuel [22]. The suggested mixture ratios range from 10 to 97 vol.-% pyrrole and 13 to 19 vol.-% ethylene imine. A mixture of 80% pyrrole and 20% ethylene imine has a melting point of 223 K (–50 °C) and has an ignition delay of only 7 ms with white fuming nitric acid (WFNA) at 297 K (24 °C) and an ignition delay of 11 ms at 233 K (–40 °C).

#### 2.1.4 Toxicity of Ethyleneimine

Aziridines are highly toxic, which can likely be attributed to the alteration of nucleic acids, proteins, and other vital biochemicals by alkylation. Substances derived from aziridines but no longer containing the aziridine ring (e.g., polyethyleneimines) are normally of low toxicity.

The handling of ethylene imine requires special safety precautions. Ethyleneimine spilled on unprotected skin causes severe chemical burns with long-lasting burn scars. Inhalation of ethyleneimine vapors causes vomiting with nausea continuing for hours afterward. The compound is a potent carcinogen. It is classified as an A2 proved animal carcinogen and suspected human carcinogen. Ethyleneimine is a mutagen that has a positive Ames test [23].

The conversion factor for permissible exposure limits in air is 1 ppm = 1.76 mg/m<sup>3</sup> at 25 °C and 1 atm. The American Conference of Governmental Industrial Hygienists (ACGIH) at one time recommended a threshold limit value (TLV) of 0.5 ppm (0.09 mg/m<sup>3</sup>) and a time-weighted average (TWA) of 0.1 ppm (0.18 mg/m<sup>3</sup>), with skin contact to be always avoided. Nonetheless, exposure of this chemical to workers should be controlled through the required use of best possible engineering controls, careful work practices, and personal protective equipment, including respirators. Protective Action Criteria (PAC) are Temporary Emergency Exposure Limit (TEEL-0): 0.05 ppm; PAC-1: 0.1 ppm; PAC-2: 4.6 ppm; PAC-3: 9.9 ppm. Worker exposure must be limited to the lowest feasible concentration. The National Institute for Occupational Safety & Health (NIOSH) Immediately Dangerous to Life or Health (IDLH) concentration is 100 ppm. In acute toxicity tests with test animals, the lethal dose LD50 (oral, rat) was 14 mg/kg, LD50 (skin, rabbit) was 13 mg/kg, and lethal concentration LC50 (10-min. inhalation, mouse) was 2236 ppm.

Ethyleneimine is one of the 13 Occupational Safety and Health Administration (OSHA)-regulated carcinogens, as listed in NIOSH Pocket Guide to Chemical Hazards [24].

### 2.1.5 Fire Hazard Properties of Ethyleneimine

The flammable range of ethyleneimine in air is from 3.6 to 46 vol.-%. The auto-ignition temperature is 593 K (320 °C).

## 2.2 Diaziridine

Diaziridine, a cyclic hydrazine, is hydrogenated diazomethane (diazirine), which is extremely hazardous in its explosive and toxic properties. It is usually only prepared in solutions. Diaziridine is unstable and not suitable as a rocket propellant. Alkyl-diaziridines are somewhat more stable [25].

## 2.3 Triaziridine

Triaziridine, cyclotriazane,  $N_3H_3$ , has not yet been synthesized in the pure state. It was found as an inclusion in a silver zeolite treated with ammonia. It is a very energetic molecule like hydrazine.

The molecular structure of a series of nitro-triaziridines was studied as high-energy-density compounds using a density functional theory (DFT) method [26]. The HOFs, bond dissociation energies (BDE), and detonation performance were calculated. It was found that all nitro-triaziridines have highly positive  $\Delta H_f$ 's, and the electron-withdrawing action of nitro groups, the steric hindrance, and N—N bonds have a positive effect on increasing values of  $\Delta H_f$ . The thermodynamic stability was estimated by BDE and available free space per molecule in a unit cell.

The unsubstituted parent compound remains elusive, however, the *cis*- and *trans*-2,3-dialkyl-substituted triaziridines were reported. *Ab initio* quantum chemical computations of substituent effects, including stabilization by participation in aromatic rings, were performed on triaziridine strain energy and HOF in the hope of predicting more stable derivatives of this compound [27]. It may be possible to stabilize  $N_3H_3$  by sandwiching it with a triangular boron hydride and forming an  $N_3(BH_2)_3$  adduct.

Cyclotriazane exists only when stabilized in a lattice of silver zeolite [28] but its existence has been questioned [29]. The potential energy surface of the  $N_3H_3$  molecule was examined by *ab initio* calculations and five stable isomers of  $N_3H_3$  were identified. It may be possible to stabilize triazirine in low-temperature argon matrices.

The gas-phase thermal decomposition of difluorodiazirine according to the reaction

has been studied in a static system in the temperature range of 396–443 K (123–170 °C) and a pressure range of 13–106 kPa (100–800 mm Hg) [30]. The primary decomposition, yielding nitrogen and difluorocarbene, appeared to be unimolecular and homogeneous. The rate constant was pressure dependent in the pressure range studied. At a total pressure of 27 kPa (200 mm Hg), the first-order rate constants would fit the Arrhenius equation

$$k = 0.68k_\infty = 1013.1 \pm 0.4 \exp\left(\frac{-32200 \pm 700}{RT}\right) \text{ s}^{-1}.$$

The activation energy calculated from extrapolated values of  $k_\infty$  at 396 and 443 K (123 and 170 °C) agreed within limits of experimental error with that obtained from values of  $k$  at 27 kPa (200 mm Hg).

### 3 Four-Membered Ring Amines

Propyleneimine, also known as trimethyleneimine, azacyclobutane, azetidine, aze-tane, and CAS RN [503-29-7] is miscible with water, boils at 334–335 K (61–62 °C), and has a density of 0.847 g/cm<sup>3</sup> at 298 K (25 °C). Azetidine is rarely used in the chemical industry. We were tempted to skip the discussion of four-membered ring amines at this point because azetidine itself is not easily obtained. There are several azetidine derivatives of interest as rocket fuels and explosives, so let us continue.

The enthalpy of formation of azetidine was predicted by *ab initio* calculations [31].

The most important azetidine derivative is 1,3,3-trinitroazetidine, also known as C<sub>3</sub>H<sub>4</sub>N<sub>4</sub>O<sub>6</sub>, TNAZ, CAS RN [97645-24-4] which has been thoroughly investigated as a new HEDM with improved sensitivity characteristics (improved over RDX). The properties of TNAZ and its salts are discussed here.

Inserting more than one nitrogen atom into a four-membered saturated ring leads to structural isomers, one is a bifunctional ring-closed symmetrical secondary amine and the other with vicinal nitrogen atoms is a ring-closed hydrazine:

1,3-diazetidine    1,2-diazetidine

1,2-Dimethyldiazetidine has been proposed as a rocket fuel [32]. 1,2-Dimethyldiazetidine can be prepared from symmetrical dimethylhydrazine (SDMH) and ethylene bromide. It freezes at 183 K ( $-90^{\circ}\text{C}$ ) and boils at 343 K ( $+70^{\circ}\text{C}$ ), has a density of  $0.8099\text{ g/cm}^3$ , and has a refractive index  $n_D^{25} = 1.4130$ .

Inserting one or more nitrogen atoms into a four-membered unsaturated ring (cyclobutadiene) leads to structural isomers, the predicted stability of which decreases in the order cyclobutadiene > 1,3-diazete > azete (azacyclobutadiene) > 1,2-diazete > triazete > tetraazete [33]:

cyclobutadiene > azete (azacyclobutadiene) > 1,2-diazete > triazete > tetraazete

With successive aza-substitution, the difference in the energies of the substituted cyclobutadienes and the corresponding aza-substituted tetrahydrofurans decreases. 1,3-Diazete is a theoretical dimer of hydrocyanic acid but has not been found via this route. Polyheteroatomic rings consisting only of nitrogen or phosphorus atoms can be stabilized by the introduction of acceptors of the unshared electron pair of the heteroatom, particularly oxygen atoms, with the formation of oxo compounds [34].

Tetraazetetrahedrane,  $\text{N}_4$ , is 11.3 kJ/mol lower in energy than tetrazete, in contrast to its hydrocarbon analogue, tetrahedrane, which has 108.9 kJ/mol higher energy than that of cyclobutadiene. The open-chain  $C_s$  structure of tetranitrogen (having the triplet ground state) is predicted to be the most stable isomer of  $\text{N}_4$ . Its energy is 62.0 kJ/mol lower than that of tetrazete. The predicted enthalpies of formation,  $\Delta H_{298}^f$ , of tetraazetetrahedrane, tetrazete, and the open-chain tetranitrogen are  $732.5 \pm 8.0$  kJ/mol,  $746.5 \pm 7.6$  kJ/mol, and  $686.6 \pm 7.6$  kJ/mol, respectively [35]. Tetraazetetrahedrane has yet to be synthesized and stabilized.

### 3.1 3,3-Dinitroazetidine

The two hydrogens in the 3,3-position on the carbon atom in azetidine can be substituted with geminal nitro groups, which interestingly somewhat stabilizes the strained ring.

Azetidine    3,3-Dinitroazetidine

One wonders about the huge amount of attention devoted to TNAZ when its lesser nitro analog 3,3-dinitroazetidine (also called propanedinitroimine) can be prepared with much less effort [36]:

(see also [37] and [38]). 3,3-Dinitroazetidine should be evaluated further as a propellant ingredient.

### 3.1.1 Salts of 3,3-Dinitroazetidine

3,3-Dinitroazetidine is an explosive in its own right. Its explosive power and oxygen balance can be improved by forming the dinitramide salt of the amine, called dinitroazetidinium dinitramide [39]. 3,3-Dinitroazetidine contains only two nitro groups instead of three. This compound has a secondary amine  $-\text{NH}-$  group instead of a nitramine group and behaves like an amine. It forms salts with strong acids. Salts with oxidizing acids are of interest as energetic additives.

The pressure-temperature phase diagram for 3,3-dinitroazetidinium dinitramide (DNAZ-DN) has been measured using a high-pressure diamond anvil cell with Fourier transform infrared spectroscopy (FTIR), Raman spectroscopy, and optical polarizing light microscopy [40]. The phase diagram was determined between ambient pressure and 10.0 GPa over the temperature range from 198 K ( $-75^\circ\text{C}$ ) to decomposition temperatures above 423 K ( $150^\circ\text{C}$ ). The phase diagram delineates the melt curve for  $\alpha$ -DNAZ-DN, a reversible, pressure-induced phase transformation in  $\alpha$ -DNAZ-DN forming a new high-pressure polymorph called  $\beta$ -DNAZ-DN. Additional measurements provided the pressure and temperature conditions for solid-state decomposition of  $\beta$ -DNAZ-DN. FTIR and Raman spectra were obtained for both the  $\alpha$  and  $\beta$  phases as a function of pressure at room temperature. The new high-pressure  $\beta$ -polymorph could not be retrieved after lowering the pressure to ambient conditions.  $\alpha$ -DNAZ-DN is orthorhombic with  $C_{m21}$  symmetry and has a density of  $1.791\text{ g/cm}^3$ . The polymorphs' stability fields are as follows: **(1)** the orthorhombic phase,  $\alpha$ -phase, is stable between atmospheric pressure and 1.05 GPa from 198 to 409 K ( $-75$  to  $+136^\circ\text{C}$ ); **(2)** the liquidus phase is stable from atmospheric pressure to 1.0 GPa between 409 to 419 K ( $136$  to  $146^\circ\text{C}$ ); **(3)** the high-pressure polymorph,  $\beta$ -phase is stable above 1.0 GPa between 223 K ( $-50^\circ\text{C}$ ) and up to incipient decomposition temperatures. Between 1.1 and 10.0 GPa and 198 and 423 K ( $-75$  and  $+150^\circ\text{C}$ ),  $\beta$ -DNAZ-DN is the stable phase. A similar paper by the same authors on ammonium dinitramide (ADN) has previously been published. The crystal structures of 3,3-dinitroazetidinium dinitramide **(1)**, and 1-*iso*-propyl-3,3-dinitroazetidinium dinitramide **(2)**, have been determined [41].

3,3-Dinitroazetidinium dinitramide **(1)** crystallizes in the orthorhombic space group  $C_{mc}2_1$  with unit cell dimensions  $a = 9.932(1) \text{ \AA}$ ,  $b = 8.545(1) \text{ \AA}$ ,  $c = 11.107(1) \text{ \AA}$ , while **(2)** crystallizes in the orthorhombic space group  $Pbca$  with cell dimensions  $a = 11.464(2) \text{ \AA}$ ,  $b = 11.657(2) \text{ \AA}$ ,  $c = 17.916(4) \text{ \AA}$ . Compound **(2)** formed spontaneously from **(1)** by reacting with the solvent, acetone, during attempts to recrystallize it.

$^2\text{H}$ -,  $^{13}\text{C}$ -, and  $^{15}\text{N}$ -labeled isomers of 1,3,3-trinitroazetidine and 3,3-dinitroazetidinium nitrate were synthesized by using appropriately labeled starting materials and characterized by nuclear magnetic resonance (NMR) and mass spectral analysis [42]. Unequivocal assignments of all NMR chemical shifts of the unlabelled title compounds and their intermediate precursors were facilitated by the NMR spectra of the labeled compounds along with carbon-hydrogen correlation experiments.

The 3,3-dinitroazetidinium (DNAZ) salt of perchloric acid ( $\text{DNAZ} \cdot \text{HClO}_4$ ) was characterized by elemental analysis, IR, NMR, and X-ray diffraction (XRD) [43]. The thermal decomposition of  $\text{DNAZ} \cdot \text{HClO}_4$  was investigated with constant heating rates by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA)/differential thermogravimetry (DTG). The results showed that the thermal decomposition process of  $\text{DNAZ} \cdot \text{HClO}_4$  is a two-stage process. The apparent activation energy ( $E_a$ ) and pre-exponential factor ( $A$ ) of the exothermic decomposition reaction of  $\text{DNAZ} \cdot \text{HClO}_4$  were  $156.47 \text{ kJ/mol}$ , and  $10^{15.12} \text{ s}^{-1}$ , respectively. The critical temperature of the thermal explosion is  $461.6 \text{ K} = 188.5^\circ\text{C}$ . The values of  $\Delta S$ ,  $\Delta H$ , and  $\Delta G$  of this reaction are  $42.26 \text{ J mol}^{-1} \text{ K}^{-1}$ ,  $154.44 \text{ kJ mol}^{-1}$ , and  $135.42 \text{ kJ mol}^{-1}$ , respectively.

### 3.2 1,3,3-Trinitroazetidine

1,3,3-Trinitroazetidine, also known as TNAZ,  $\text{C}(\text{NO}_2)_2(\text{CH}_2)_2\text{NNO}_2$ ,  $\text{C}_3\text{H}_4\text{N}_4\text{O}_6$ , CAS RN [97645-24-4],  $M = 192.088 \text{ g/mol}$ , with a four-membered ring, is a very energetic additive and has been investigated as an explosive in its own right. The oxygen balance of TNAZ is  $-16.66\%$  and the nitrogen content is  $29.2 \text{ mass-\% N}$ . TNAZ was first synthesized in 1983 and has received a very thorough examination in the interim. Here we are mostly interested in evaluating it as an energetic additive to rocket propellants. It remains to be seen if replacing RDX in nitramine propellants with TNAZ brings any benefit to propellant properties and can be justified given the increased costs. The de-

velopment of TNAZ as an explosive may continue but it is unlikely to become a major achievement for propellant formulations. Over time, interest in TNAZ has been lost because of some drawbacks such as the high cost of the product and high volatility.

1,3,3-Trinitroazetidine is both a nitro compound and a nitramine and the ring structure is a heterocyclic amine. Therefore, one must decide if it should be discussed here, under heterocyclic amines within the chapter dealing with its parent molecule, azetidine, or in the chapter on nitramines. We opted to place it here under heterocyclic amines, the parent structure of TNAZ.

TNAZ has a melting point of 374 K (101 °C), a crystal density of 1.84 g/cm<sup>3</sup>, and good thermal stability up to 513 K (240 °C). It has a slightly negative oxygen balance for complete combustion to CO<sub>2</sub>, -16.7%. It is only half as sensitive to impact as HMX (with twice the drop height required to set it off). Its disadvantage is high production costs and slight volatility.

### 3.2.1 Preparation of TNAZ

When TNAZ was first synthesized in 1983, it was the result of a multi-step synthesis and the yield was only 5% [44, 45]. One of the first processes used for the synthesis of TNAZ started with epichlorohydrin and *tert*-butylamine. Direct nitrolysis of 3-substituted azetidinium hydrochlorides with acetyl nitrate produces cyclic nitramines. In the meantime, several other synthesis methods have been developed and the price has dropped somewhat. TNAZ was manufactured on a pilot plant scale at Thiokol and its cost continues to drop. Until 1991, TNAZ had only been prepared in laboratories in half-pound batches. As a next step, a process demonstration module facility was completed at Picatinny Arsenal to prepare it in multi-pound batches [46].

1,3,3-Trinitroazetidine can be prepared by reacting 1,3,5-trialkyl hexahydrotriazine and tris(hydroxymethyl)nitromethane, and after following several intermediate steps by converting 1-alkyl-3,3-dinitroazetidine into 1,3,3-trinitroazetidine [47]. Another 8-step synthesis of TNAZ involved the condensation of tris-(hydroxymethyl)-nitromethane with *tert*-butylamine and formaldehyde to yield 3-*tert*-butyl-5-hydroxymethyl-5-nitrotetrahydro-1,3-oxazine [38]. This was treated with methanolic HCl to yield 2-*tert*-butylaminomethyl-2-nitro-1,3-propane diol hydrochloride. The cyclized azetidine ring was achieved with excellent reproducibility

by the effect of diisopropyl azodicarboxylate (DIAD), which was subsequently treated with NaOH and oxidatively nitrated to yield 1-*tert*-butyl-3,3-dinitroazetidine (BDNA). The nitrolysis of BDNA with  $\text{NH}_4\text{NO}_3$  and  $\text{Ac}_2\text{O}$  yielded TNAZ in 57% overall yield.

(See also [48].) The electrophilic addition of  $\text{NO}^+\text{NO}_2^-$  across the highly stressed C—N bond of 1-aza-bicyclo[0,1,1]butane eventually leads to TNAZ [49]. A group of chemists in China described a method also starting with epichlorohydrin and *tert*-butylamine [50].

The group at Fraunhofer Institute of Chemical Technology (ICT) perfected the Hiskey method for the synthesis of TNAZ [51]. The overall yield of the five-step procedure was 15–20%.

A review of more than 16 routes for TNAZ synthesis revealed that the total yield of the most technologically successful of these synthesis routes does not exceed 30% of theory [52]. It was stated that TNAZ is a highly energetic material, more powerful than RDX, and which may be less vulnerable than most other nitramines. This makes it suitable for applications as a castable explosive as well as a plasticizer. However, a relatively high vapor pressure, volume contraction, and formation of shrinkage cavities in the solidification of its melt can be a minor disadvantage of TNAZ.

When the original synthesis method of TNAZ was scaled up to produce several hundred kg of TNAZ for evaluation by the DoD, it produced significant amounts of chemical waste (over 1200 kg waste per kg of TNAZ), including large quantities of halogenated solvents. An alternate synthesis method, which gave much higher yields of TNAZ and left less waste than generated by the original process, was developed at the Los Alamos National Laboratory and transferred to Aerojet, Sacramento, where it was scaled up to production-plant quantities to give TNAZ in 57% overall yield [53]. The new process produced only about 10% of the waste produced in the original process without recycling solvents or reagents.

Other methods are described for synthesizing 1,3,3 trinitroazetidine [54]. Another synthesis method for TNAZ starts with nitromethane and formaldehyde, cheap raw materials, via a five-step process [55]. The overall yield was above 40%. A review of routes for TNAZ synthesis developed since 1990 was presented in [56] (see also [57]).

The most popular route to TNAZ now seems to be one where the first step is to make 3-*tert*-butyl-5-hydroxymethyl-5-nitrotetrahydroxy-1,3-oxazine by reacting a solution of paraformaldehyde, NaOH, nitromethane, and *tert*-butylamine [58]. This eventually leads to TNAZ using the scheme demonstrated earlier. It was shown that TNAZ was significantly more sensitive to mechanical stimuli than 2,4,6-trinitrotoluene (TNT).

1,3,3-Trinitroazetidine was synthesized using an alternative approach based on the transformation of 3-oximino-1-(*p*-toluenesulfonyl)azetidine in the reaction with nitric acid through an intermediate pseudonitrol [59]. Nitrolysis of *N-tert*-butyl-3,3-dinitroazetidinium nitrate with  $\text{NH}_4\text{NO}_3/\text{Ac}_2\text{O}$  at a reaction temperature of 353 K (80 °C) gives TNAZ with a yield of 83.1% [60].

### 3.2.2 Physical Properties of TNAZ

The physical properties of TNAZ are summarized in Table 2.

**Table 2:** Physical properties of TNAZ.

| Property                                      | S.I. Units             | Other units                    | References |
|-----------------------------------------------|------------------------|--------------------------------|------------|
| Molecular mass                                | 192.0871 g/mol         | 5.206 mol/kg                   | [14]       |
| Melting point                                 | 373.8 K                | 100.7 °C                       |            |
| Density                                       | 1.84 g/cm <sup>3</sup> |                                |            |
| Enthalpy of formation                         | +36.17 kJ/mol          | +8.644 kcal/mol<br>= +45 cal/g | [61]       |
|                                               | +189.50 kJ/kg          | +45.29 kcal/kg                 | [62]       |
| Heat of fusion                                | 29 kJ/mol              | 6.93 kcal/mol                  | [63]       |
| Heat of vaporization (from the melt at 393 K) | 66.8 kJ/mol            | 15.96 kcal/mol                 | [63]       |
| Heat of sublimation (at 373 K)                | 95.3 kJ/mol            | 22.8 kcal/mol                  | [63]       |

Enthalpy of formation data reported in existing literature varies widely from +8.79 to +457.7 kJ/mol, thus making it difficult to find an accurate number. See also [64–67].

### 3.2.2.1 Melting Point and Phase Diagrams of TNAZ

The peak temperature of the melting endotherm of TNAZ was 375.69 K (102.54 °C) and the enthalpy of melting was  $30.31 \pm 0.30$  kJ/mol ( $7.24 \pm 0.07$  kcal/mol) [68].

The phase diagrams of TNAZ in mixtures with other energetic materials have been investigated to see if the properties (as melt-castable explosives in particular) could be improved by adding another component. Components analyzed in TNAZ mixtures included HMX [69], 1,3-dinitro-3-(1',3'-dinitroazetidin-3'-yl)azetidine (TNDAZ) [70], *N*-acetyl-3,3-dinitroazetidine (ADNAZ) [71], and *N*-nitroso-3,3-dinitroazetidine [72].

1,3,3-Trinitroazetidine and TNT form a eutectic mixture with a melting temperature of 60.6 °C containing 35.3 mol-% TNAZ [73]. The binary system 1,3,3-trinitroazetidine (TNAZ)/1,3,5-trinitrobenzene (TNB) had an area with at least three eutectic points from different phase modifications of TNB and/or TNAZ at 341.5 K (68.4 °C) with 53.4% TNAZ, at 336.7 K (63.6 °C) with 47.8% TNAZ, and at 335.1 K (62.0 °C) with 45.6% TNAZ [74].

Another energetic azetidine derivative is 3-azido-1,3-dinitroazetidine (AzDNAZ). Melting point measurements of TNAZ/AzDNAZ mixtures with different TNAZ contents revealed a eutectic composition TNAZ/35/65 with a melting point of 334 K (61 °C) [75]. Combined introduction of nitro- and azido groups followed by nitration of tBuDNAZ/tBuAzNAZ mixtures in  $\text{N}_2\text{O}_5/\text{CH}_3\text{CN}$  or  $\text{NH}_4\text{NO}_3/(\text{CH}_3\text{CO})_2\text{O}$  systems opens up the possibility of synthesis TNAZ/AzDNAZ mixtures.

### 3.2.2.2 Vapor Pressure of TNAZ

One disadvantage of TNAZ is its high volatility. The vapor pressure can be calculated in the widened temperature interval (373–773 K = 100–500 °C):

$$\ln p = -7591/(T - 11.33)$$

where  $p$  is the pressure in MPa and  $T$  is the temperature in kelvin. The dependence detailed yields a TNAZ boiling point at an atmospheric pressure of 548 K (275 °C) and heat of evaporation of 63.1 kJ/mol [76].

### 3.2.2.3 Solubility of TNAZ

Solubility information can be useful for purifying and recrystallizing energetic materials. The solubility of TNAZ in ethanol-water binary solvent mixtures was determined from 293 to 323 K [77]. The results revealed that the solubility of TNAZ in ethanol-water binary solvent mixtures increased with an increase in temperature. In the pure ethanol solvent, the solubility increased from 0.01349 to 0.03935 mol/mol with a temperature increase from 293 to 323 K.

### 3.2.2.4 Thermal Conductivity of TNAZ

The heat capacity, thermal conductivity, and thermal diffusivity of a range of other oxidizers, binders, and rocket propellants were determined and compared to data in existing literature [78]. The thermal diffusivity  $\alpha$  of TNAZ for the range from 293 to 361 K (20 to 88 °C) can be described by the linear equation

$$\alpha = 1.51 \times 10^{-3} - 3.36 \times 10^{-6}t$$

where  $\alpha$  is the thermal diffusivity in  $\text{cm}^2/\text{s}$  and  $t$  is the temperature in °C. The thermal conductivity  $\lambda$  of TNAZ in the range from 293 to 361 K (20 to 88 °C) can be described by the linear equation

$$\lambda = 0.841 \times 10^{-3} - 25.7 \times 10^{-7}t$$

where  $\lambda$  is the thermal conductivity in  $\text{cal cm}^{-1} \text{s}^{-1} \text{°C}^{-1}$  and  $t$  is the temperature in °C.

### 3.2.2.5 Thermodynamic Properties and Thermal Properties of TNAZ

#### Heat Capacity of TNAZ

The heat capacity of TNAZ near room temperature is  $1.372 \text{ J g}^{-1} \text{ K}^{-1}$  ( $0.328 \text{ cal g}^{-1} \text{°C}^{-1}$ ) [78].

#### HOF and Heat of Combustion of TNAZ

The standard enthalpy of formation of TNAZ is  $\Delta H_f +36.4 \text{ kJ/mol} = +189.50 \text{ kJ/kg} = 8.70 \text{ kcal/mol} = +45.29 \text{ cal/g}$  [62]. Other sources gave a  $\Delta H_f$  of  $280 \text{ kJ/kg}$  [51].

#### Heat of Fusion and Solid-State Phase Transitions of TNAZ

The heat of fusion of TNAZ at 372–375 K (99–102 °C) was  $30.31 \pm 0.30 \text{ kJ/mol}$  [68]. Other sources have reported a heat of fusion of  $29.45 \text{ kJ/mol}$  ( $6.93 \text{ kcal/mol}$ ) [63, 79].

### 3.2.2.6 Molecular Structure of TNAZ

TNAZ crystallizes with unit cell parameters of  $a = 5.7580(6) \text{ Å}$ ,  $b = 11.1309(12) \text{ Å}$ ,  $c = 21.524 \text{ Å}$ ,  $\alpha = 90^\circ$ ,  $\beta = 90^\circ$ ,  $\gamma = 90^\circ$ ,  $V = 1379.5 \text{ Å}^3$ , and  $Z = 8$ ,  $\rho_{\text{XRD}} = 1.850 \text{ g/cm}^3$  [58, 70]. This thermal data supported the existence of more than one polymorph for TNDZ and for TNAZ. A structural relative of TNAZ is 1,3-dinitro-1,3-diazetidine, DNAD, CAS RN [78246-06-7], which is also an explosive substance.

### 3.2.2.7 Optical, Electrical, and Magnetic Properties of TNAZ

#### Absorption Spectra of TNAZ

The IR spectrum of TNAZ with absorption peaks at 3036, 1596, 1540, 1332, 1278, 1016, 842, 762, and  $665 \text{ cm}^{-1}$  is shown in Figure 2. Infrared spectra were obtained and normal co-ordinate calculations were made for TNAZ and *N*-acetyl-3,3-dinitroazetidine (ADNAZ) to learn more about the conformational behavior of these compounds and to make assignments of the IR bands to the appropriate normal modes of vibration

**Figure 2:** IR spectrum of TNAZ in a KBr pellet. (Reprinted and modified from [58], with permission from ©2004 Elsevier; permission conveyed through RightsLink.)

[80]. Semi-empirical molecular orbital (MO) calculations were then made to obtain additional information about the molecular structures.

### 3.2.3 Chemistry of TNAZ

#### 3.2.3.1 Salt Forming Reactions with TNAZ

TNAZ is a base with a  $pK_a = 6.5$  and forms salts with strong acids. Salts formed with strongly oxidizing anions and highly energetic anions are of prime interest as propellant and explosive ingredients. The properties of TNAZ salts are summarized in Table 3. A unique combination is the salt formed from TNAZ base and NTO acid. Both of these parent compounds are new HEDMs developed during the early 1990s.

**Table 3:** Physical properties of trinitroazetidinium salts.

| Compound                                                | Gross formula                                                | Molecular mass<br>g/mol | Melting point |     | Density<br>g/cm <sup>3</sup> | Enthalpy of formation |              |
|---------------------------------------------------------|--------------------------------------------------------------|-------------------------|---------------|-----|------------------------------|-----------------------|--------------|
|                                                         |                                                              |                         | K             | °C  |                              | kJ/mol                | kcal/mol     |

### 3.2.3.2 Thermal Stability of TNAZ

#### Experimental Studies of Slow Thermal Decomposition of TNAZ

Photofragmentation translational spectroscopy was used to study fragments shed during the incipient decomposition of TNAZ. This was carried out to try and identify the weakest link in the molecule, the one that breaks first [81]. In this method, vapors of the molecule of interest are expanded from a nozzle into a vacuum. The expansion is then collimated to form a molecular beam. The molecular beam is crossed with the output of a pulsed CO<sub>2</sub> laser which excites the molecule of interest above the dissociation threshold, relying on infrared multi-photon excitation to induce decomposition. To dissociate, a molecule must absorb approximately 20 infrared photons. TNAZ easily fragments upon ionization. All time-of-flight (TOF) mass spectra were consistent with the sequential loss of two NO<sub>2</sub> groups. Following this loss, the remaining fragment decomposes into C<sub>3</sub>H<sub>4</sub> and N<sub>2</sub>O<sub>2</sub>.

The mechanism and reaction kinetics of the thermal decomposition of TNAZ and (separately) its key decomposition intermediate, 1-nitroso-3, 3-dinitroazetidine (NDNAZ), were studied at varying temperatures and at a range of isothermal temperatures at 10 °C intervals from 393–433 K (120–160 °C) for NDNAZ and 433–483 K (160–210 °C) for TNAZ using a simultaneous thermogravimetric modulated beam mass spectrometer (STMBMS) [82]. TNAZ decomposed via four separate routes, one of which led to NDNAZ, which subsequently decomposed via at least two distinct routes.

The apparent activation energy of TNAZ decomposition was 133 kJ/mol and the pre-exponential constant was 10<sup>9.8</sup> s<sup>-1</sup>. For comparison, the activation energy of RDX decomposition was 134.7 kJ/mol and for HMX it was 380.9 kJ/mol. The critical temperature of the thermal explosion was calculated as 511–523 K [68]. The thermal stability of TNAZ and that of six other explosives was measured by a thermogravimetric analysis-mass spectrometry (TGA-MS) combination (STMBMS). The results were compared to develop a kinetic model and to identify the rate-determining steps [83, 84].

A fused-silica capillary column with a narrow internal diameter and a stationary phase was used for the simultaneous gas chromatography-mass spectrometry (GC-MS) determination of N<sub>2</sub>, O<sub>2</sub>, CO, CO<sub>2</sub>, NO, NO<sub>2</sub>, (CN)<sub>2</sub>, and H<sub>2</sub>O from the thermal decomposition of TNAZ [85]. The detection of hydrogen cyanide and cyanogen gases as products of TNAZ thermal decomposition was reported for the first time.

The thermal behavior of TNAZ was studied by using DSC, differential thermal analysis (DTA), and TGA [79]. Data indicated that TNAZ is thermally more stable than RDX but less stable than HMX and TNT. The reaction of intense thermal decomposition started at 456–503 K (183–230 °C) (depending on the heating rate) while the first exothermic reaction was observed at 451 K (178 °C) at a heating rate of 1 °C/min. By applying multiple heating rate DSC measurements and Ozawa's method, the activation energy of 161.3 kJ/mol, and a pre-exponential factor of 8.27 × 10<sup>13</sup> 1/s were calculated from the DSC peak maximum temperature-heating rate relationship.

The thermal decomposition kinetics of TNAZ have been measured using non-isothermal DSC [86]. Samples of TNAZ in open pans and pierced pans underwent mainly melting ( $\Delta H_{\text{fus}} = 27 \pm 3 \text{ kJ/mol}$ ) and vaporization ( $\Delta H_{\text{vap}} = 74 \pm 10 \text{ kJ/mol}$ ) during heating. However, when confined in sealed high-pressure crucibles, exothermic thermal decomposition was observed. The activation energy for thermal decomposition of  $184 \text{ kJ/mol}$  at the start of the reaction decreased to  $38 \text{ kJ/mol}$  near the end of the reaction. The rates clearly exhibit acceleratory behavior that was ascribed to autocatalysis. The measured heat release of thermal decomposition ( $Q = 640 \pm 150 \text{ kJ/mol}$ ) was independent of the heating rate and the sample mass.

Based on computer models, two pathways can be initiated by the fission of the  $\text{N}-\text{NO}_2$  and  $\text{C}-\text{NO}_2$  bonds to yield radical intermediates, while the other two pathways involve the molecular elimination of  $\text{HONO}$  [87]. Energy profiles for the pathways and possible routes to some of the experimentally observed species of TNAZ decomposition were calculated. The energy required to initiate the  $\text{NO}_2$  bond fission pathways is  $4\text{--}8 \text{ kcal/mol}$  lower than the  $\text{HONO}$  elimination pathways. In the gas phase, the  $\text{NO}_2$  elimination pathways were predicted to be the dominant routes for TNAZ decomposition. In the condensed phase, however, this trend may be reversed.

The DSC, TGA, and DTG curves of TNAZ demonstrated in Figure 3 show an endothermic melting peak at  $373 \text{ K}$  ( $100^\circ\text{C}$ ) accompanied by steady evaporation TGA weight loss [58]. The DTA baseline decreased steadily between approximately  $393$  and  $453 \text{ K}$  ( $120$  and  $180^\circ\text{C}$ ), thus reflecting the endothermic nature of TNAZ evaporation. The curve revealed decomposition of TNAZ at  $378\text{--}407 \text{ K}$  ( $105\text{--}134^\circ\text{C}$ ) with a weight loss of  $10\%$ . The complete loss of sample was observed due to evaporation/decomposition over the temperature range  $376\text{--}467 \text{ K}$  ( $103\text{--}194^\circ\text{C}$ ), and the onset of exotherm was at  $453 \text{ K}$  ( $180^\circ\text{C}$ ).

**Figure 3:** DSC, TGA, and DTG curves of TNAZ. (Reprinted and modified from [58], with permission from ©2004 Elsevier; permission conveyed through RightsLink.)

**Figure 4:** DSC thermogram of TNAZ. (Republished and modified from [88], with the permission of ©2005 John Wiley & Sons – Books; permission conveyed through Copyright Clearance Center, Inc.)

In the DSC, the melting endotherm of TNAZ started at 371.8 K (98.7°C) and maxed at 372.6 K (99.5°C). The decomposition exotherm started at 473 K (200°C) and maxed at 526 K (253°C), as demonstrated in Figure 4 [88].

The thermal decomposition of TNAZ in the gas phase, and in the molten state in dilution with *m*-dinitrobenzene in a wide concentration range (5–80%), was studied by manometry, volumetry, thermogravimetry, IR, and MS [59, 89]. The gas-phase reaction at 443–493 K (170–220 °C) followed first order of kinetics and obeyed Arrhenius equation with an activation energy of 169 kJ/mol (40.5 kcal/mol) and a logarithm of pre-exponential factor of 15.6. The complete TNAZ decomposition at 493 K (220 °C) resulted in the formation of nitrogen, nitrogen dioxide, carbon dioxide, nitroacetaldehyde, and traces of CO and NO. The rate-determining step of the process is the homolytic cleavage of the N–NO<sub>2</sub> bond in the TNAZ molecule. In a melt at 443–483 K (170–210 °C), the thermal decomposition proceeded with a pronounced self-acceleration and the maximum reaction rates were observed at conversions of 53.9–67.4%. The solid decomposition products auto-accelerated the reaction. It is most likely that the autocatalysis of TNAZ decomposition in the liquid phase is due to the autocatalytic decomposition of 1-nitroso-3,3-dinitroazetidine, which is formed by the thermal decomposition of TNAZ. In *m*-dinitrobenzene solution, TNAZ also decomposed with self-acceleration. It was found that the higher the concentration in the solution, the more pronounced the self-acceleration.

Based on the initial temperature at which DSC curves deviate from the baseline and the onset temperature and maximum peak temperature from the non-isothermal

DSC curves of TNAZ at different heating rates, the thermal decomposition activation energy and pre-exponential constant were obtained. Kissinger's method and Ozawa's method, were employed to facilitate this and also the values of heat capacity were obtained by microcalorimetry [90]. The thermal explosion temperature, adiabatic time-to-explosion, 50% drop height (H50) of impact sensitivity, and the critical temperature of hot-spot initiation of TNAZ were calculated. The data showed that **(1)** TNAZ is thermally stable; **(2)** its impact sensitivity is better than that of cyclotrimethylene trinitramine (RDX); **(3)** the critical temperature of hot-spot initiation is higher than that of RDX and between those of triaminotrinitrobenzene (TATB) and hexanitrostilbene (HNS).

If TNAZ is used in solid propellant combinations, it may come in contact with other energetic materials and ballistic modifiers. The compatibility of TNAZ with some common energetic materials such as HMX, RDX, nitrocellulose (NC), and nitroglycerine (NG) was tested by DSC [91]. DSC data indicated that the compatibility of TNAZ with HMX or RDX is good. However, with NC or NG it is worse than that of RDX.

### Experimental Studies of Rapid Thermal Decomposition of TNAZ

Vapors of TNAZ were pyrolyzed in a single-pulse shock tube under high dilution in Ar and over the temperature range of 750–1100 K (reflected shocks) [92]. The decay of TNAZ and the appearance of the reactive intermediate, NO<sub>2</sub>, were followed spectrophotometrically at 271 and 405 nm, respectively, in real-time via a multiple-pass quartz extension of the shock tube terminus. Major products that were generated during 1.5 ms residence time and wave quenched were identified and quantitated by gas chromatography (GC) and FTIR. The unimolecular rate constant (high-pressure limit) for the dissociation of TNAZ under these experimental conditions was

$$k_{\text{uni}} = 10^{13.96 \pm 0.63} \exp[(-19900 \pm 1190)/T] \text{ s}^{-1}.$$

Successive fissions of NO<sub>2</sub> groups were indicated by the time-dependent absorption levels at 405 nm. A gas-phase FTIR spectrum of TNAZ recorded at ~110 °C provided the missing data for computing the thermochemical parameters for this compound. The observed product distributions differed markedly from those calculated, indicating that the overall reaction was kinetically limited. A reaction mechanism consisting of 46 chemical reaction steps was proposed. Simulations based on this mechanism agreed reasonably well with the experimental results.

The initial decomposition products of laser-pyrolyzed TNAZ that were irradiated with 248 nm laser pulses were characterized using TOF mass spectrometry [93]. Products released to the gas phase were ionized by a pulse of 118 nm light, and the ions were detected using a TOF mass spectrometer. An analysis of the temperature dependence of the relative product yields showed that two reactions were important in the initial decomposition of TNAZ: unimolecular nitro-nitrite rearrangement followed by loss of NO and a bimolecular reaction generating nitrosodinitroazetidine (NDNAZ). Loss of NO<sub>2</sub> appears to be an early but not initial decomposition step. Experiments

with isotopically labeled TNAZ showed that the nitro-nitrite rearrangement occurred on the nitramine group and that  $\text{NO}_2$  was lost from both the nitroalkyl and nitramine groups.

Thin layers of solid TNAZ (initially at room temperature) were impacted by shock-waves, in an Ar or Ar/ $\text{O}_2$  medium [94]. The step functions of the pressure/temperature increments had rise-times well below microseconds. The pressure jumps ranged from 2–10 atm and the associated temperature jumps varied from 550 to 2500 K. In all these tests the elevated pressure/temperature conditions lasted for 1.5 ms.

The thermal behavior of TNAZ was studied using high-pressure DSC, which is a combination technique of *in-situ* thermolysis cell with rapid-scan FTIR and fast thermolysis probe with rapid-scan FTIR [95]. The thermal decomposition mechanism showed that the decomposition temperature of TNAZ at 1 MPa is 537.8 K (264.7 °C). Both the C– $\text{NO}_2$  and N– $\text{NO}_2$  bonds and all the other C–N, C–C, and C–H bonds of the four-membered ring of TNAZ were simultaneously broken with an increase in temperature. The gas products detected during the thermal decomposition of TNAZ consisted of  $\text{CO}_2$ ,  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ , and NO.

### Computational Studies of Thermal Decomposition of TNAZ

It was attempted to match experimental data to a computer model of TNAZ thermal decomposition [96, 97]. DFT and *ab initio* calculations were conducted to predict decomposition pathways of TNAZ initiated by unimolecular loss of  $\text{NO}_2$  or HONO [98]. The energies for  $\text{NO}_2$  elimination by N–N and C–N bond fission was 43.21 and 50.46 kcal/mol, respectively. The decomposition initiated by trans-HONO elimination can occur by a concerted H-atom and nitramine  $\text{NO}_2$  group elimination or by a concerted H-atom and nitroalkyl  $\text{NO}_2$  group elimination via barriers of 197 kJ/mol (47 kcal/mol) and 202 kJ/mol (48.27 kcal/mol), respectively. The ranking of these four decomposition steps from energetically most favored to least favored was:  $\text{NO}_2$  elimination by N–N bond fission, HONO elimination involving the nitramine  $\text{NO}_2$  group, HONO elimination involving a nitroalkyl  $\text{NO}_2$  group, and finally  $\text{NO}_2$  elimination by C–N bond fission.

The thermal decomposition of TNAZ crystals at high temperatures was modeled by molecular dynamics (MDs) simulations [99]. The change in the potential energy of TNAZ, the formation of small-molecule products and clusters during decomposition, and the initial reaction path of TNAZ were analyzed. The kinetic parameters of different reaction stages in TNAZ thermal decomposition could be obtained. The primary thermal decomposition reaction path of TNAZ was predicted to be as follows: N– $\text{NO}_2$  and C– $\text{NO}_2$  bonds broke first, then an H atom on the quaternary ring was transferred to the nitro group, and finally the C– $\text{HNO}_2$  and N– $\text{HNO}_2$  bonds broke. The main decomposition products of TNAZ were thus  $\text{NO}_2$ , NO,  $\text{N}_2$ ,  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ , and  $\text{HNO}_2$ , as well as some macromolecular clusters. The size of the cluster structure was related to the reaction temperature, decreasing in size with an increase of temperature.

### 3.2.3.3 Electron Bombardment Fission of TNAZ

TNAZ easily fragments upon electron bombardment and ionization. A study of the electron-impact (EI) fragmentation pathways of TNAZ,  $^{15}\text{N}$ , and  $^2\text{H}$  isotopically labeled compounds allowed the determination of most of the major fragmentation peaks [100]. It was found that the major pathway involves the loss of  $\text{NO}_2$  or  $\text{HNO}_2$  from the dinitroalkyl group followed by a loss of  $\text{NO}_2$  or  $\text{NO}$  from the nitramine group. The peak at  $m/e$  46,  $[\text{NO}_2]^+$ , which is the base peak, resulted primarily from N–N bond scission, while the peak at  $m/e$  30,  $[\text{NO}]^+$ , was equally likely to come from any  $\text{NO}_2$  bond. The fragmentation pathway of TNAZ showed similarities with other nitramine and nitrocarbon explosives.

### 3.2.4 Strand Burning of TNAZ

Strand burning of TNAZ, 3-azido-1-nitroazetidine (AzNAZ), and 3-azido-1,3-dinitroazetidine (AzDNAZ) in a constant-pressure bomb in the pressure range of 0.1–30 MPa and flame temperature profiles of TNAZ, AzDNAZ, and AzNAZ were measured using thin tungsten-rhenium thermocouples [76, 101]. TNAZ in the form of pressed strands of 4 mm diameter started burning at 0.4 MPa with a rate of 0.7 mm/s. Burning proceeded with a bright luminous flame, with no appreciable amount of soot and other condensed products released during combustion. The burning rate of TNAZ at 10 MPa was 17.5 mm/s, which was close to the burning rates of HMX and RDX. In the interval of 0.4–12 MPa, the burning rate law for TNAZ can be expressed as

$$r_b = 1.757p^{0.99}$$

where  $r_b$  is the burning rate in mm/s. The pressure exponent is almost equal to unity and, in combination with high volatility of TNAZ, it may be evidence of the leading role of the gas-phase chemistry in combustion.

### 3.2.5 Explosive Sensitivity of TNAZ

The shock sensitivity of pressed solid TNAZ was determined using the embedded manganin pressure gauge technique [102]. At an initial pressure of 1.3 GPa, pressure buildup (exothermic reaction) was observed after ten  $\mu\text{s}$ . At 2 GPa, TNAZ reacted rapidly and transitioned to detonation in approximately 13 mm. At 3.6 GPa, detonation occurred in less than 6 mm of shock propagation. Thus, pure TNAZ is more shock sensitive than HMX-based explosives but less shock sensitive than pentaerythritol tetranitrate (PETN) based explosives.

A 60:40 mixture of RDX/TNAZ, designated ARX-4007, had high volatility and rapidly evaporated from the liquid phase ( $>101^\circ\text{C}$ ) [103]. Hazards assessment revealed TNAZ to have an increased sensitiveness compared to TNT, while ARX-4007 was found to have sensitiveness levels that were similar to pentolite. Performance assessment of ARX-4007 as a general-purpose metal accelerating explosive gave excellent VoD (8660 m/s) and  $P_{\text{CJ}}$  (33.0 GPa) and represented substantial improvements over Composition B (7860 m/s and 29.5 GPa). TNAZ was ranked unsuitable as a TNT replacement in melt-cast systems.

TNAZ was tested as an explosive in comparison to 3,6-diamino-1,2,4,5-tetrazine-1,4-dioxide (LAX112) and 2,4-dinitroimidazole (2,4-DNI) [104]. TNAZ is useful for its performance and castability. The shock sensitivity of TNAZ was between that of pressed PETN and PBX-9501 (PBX-9501 = HMX/estane/DNPAF 95/2.5/2.5).

### 3.2.6 Toxicity of TNAZ

Genetic toxicity studies with TNAZ were initiated based on the possibility that it might convert or metabolize to a carcinogenic or mutagenic nitroso derivative [105, 106]. The following assays, capable of detecting mutations at the gene level, were employed: a bacterial (Ames Salmonella) test, an *in vitro* forward mutation assay at the hypoxanthine-guanine phosphoribosyl-transferase locus in Chinese hamster ovary (CHO) cells, and an *in vivo* cytogenetic (mouse bone marrow erythrocyte micro-nucleus) test. The results of the genetic toxicity studies indicated that TNAZ was negative in all three test systems. Thus, TNAZ was negative for the gene mutations in bacterial and mammalian cells and chromosomal mutations of mouse bone marrow erythrocytes.

## 4 Bridged, Caged, Fused, and Annulated Heterocyclic Compounds from Four-Membered Rings

The most unusual molecule that can be built from four-membered rings is cubane. Various cubane derivatives, such as nitrocubanes and aminocubanes, have already been discussed in previous sections. If one or more carbons in the cubane cube are replaced by nitrogen, and four hydrogens are replaced by nitro groups, one obtains a new class of energetic compounds, which are tetranitrotetraazacubanes.

Studies have suggested that octanitrocubane (ONC) is one of the most powerful HEDMs currently known. 2,4,6,8-Tetranitro-1,3,5,7-tetraazacubane (TNTAC) may be an even better HEDM due to its high nitrogen content and crystal density.

DFT and molecular mechanics methods were used to study the crystal structure, IR spectrum, electronic structure, thermodynamic properties, gas-phase, and condensed-phase HOF, detonation performance, and pyrolysis mechanism of TNTAC [107]. TNTAC has a predicted density of about  $2.12 \text{ g/cm}^3$ . Its predicted detonation velocity ( $10.42 \text{ km/s}$ ) and detonation pressure ( $52.82 \text{ GPa}$ ) are higher than that of ONC. The space group is  $P2_12_12_1$ , and the unit cell parameters are  $a = 8.87 \text{ \AA}$ ,  $b = 8.87 \text{ \AA}$ ,  $c = 11.47 \text{ \AA}$ ,  $Z = 4$ .

Another unusual four-membered heterocyclic ring structure was theorized but has not yet been synthesized. It consists of a central carbon atom in a spiro configuration with two rings formed by  $\text{—O—N—O—}$  atoms on either side. 2,6-Diaza-1,3,5,7-tetraoxaspiro[3,3]heptane and its dinitramine derivative, 2,6-dinitro-2,6-diaza-1,3,5,7-tetraoxaspiro[3,3]heptane, were predicted to have explosive performances that are similar to TNT or RDX [108].

## 5 Five-Membered Rings

It is interesting to follow the trend of the enthalpy of formation of cyclopentanes where one or more carbons are sequentially replaced by nitrogen. In the sequence from imidazole ( $\Delta H_{298}^f(\text{S}) = +58.5 \text{ kJ/mol}$ ) to 1,2,4-triazole ( $\Delta H_{298}^f(\text{S}) = +109 \text{ kJ/mol}$ ) to tetrazole ( $\Delta H_{298}^f(\text{S}) = +237.2 \text{ kJ/mol}$ ), the trend in the variation of their HOFs in the crystalline state is increasingly positive. The same trend is observed with their salts (their amino- and nitro-derivatives). With increasing enthalpies of formation, these compounds become more interesting as rocket propellants and explosives.

The enthalpies of formation of several imidazolium-, 1,2,4-triazolium-, and tetrazolium-based energetic salts were repeatedly calculated theoretically using different computational methods. The advances of computational chemistry have been tested in this area. At this time, there are many more computed data for the enthalpies of formation of these energetic salts than experimental measurements of the heats of combustion. The results are summarized in Tables 9 and 18, which can be found in the section on imidazolium-, 1,2,4-triazolium-, and tetrazolium-based energetic salts.

It is interesting to compare the changes in enthalpy of formation and thermal stability when one progressively replaces one carbon atom after another in a five-membered ring molecule (Table 4). From imidazole ( $\Delta H_f = +58.5 \text{ kJ/mol}$ ) to 1,2,4-triazole ( $\Delta H_f = +109.0 \text{ kJ/mol}$ ) to tetrazole ( $\Delta H_f = +237.2 \text{ kJ/mol}$ ), the enthalpies of formation get increasingly positive. Slightly different  $\Delta H_f$  numbers are shown in Table 4.

A very comprehensive 60-page summary with 387 references of azoles as energetic materials was compiled by Gao and Shreeve [109]. This is an excellent compilation of information and literature references on all kinds of energetic compounds based on nitrogen-containing five-membered heterocyclic rings. Another good source of information on azole-based energetic compounds is a dissertation [110].

**Table 4:** Effect of carbon substitution by nitrogen in five-membered ring molecules.

| Compound name                 | Imidazole                                                                         | 1,2,4-Triazole                                                                    | 4-Amino-1,2,4-triazole                                                            | Tetrazole                                                                         | 5-Aminotetrazole                                                                   |

| Decomposition temperature, K  | >530 (b.p.)                                                                       | >533 (b.p.)                                                                       | 543                                                                               | 461                                                                               | ≥479                                                                               |

The structure of heterocyclic five-membered rings of pyrrole, imidazole, 1,3,4-triazole, and tetrazole and some of their salts was examined based on their IR spectra [111]. The HOFs ( $\Delta H_f^\circ$ ) for azoles can be calculated using a semi-empirical MO theory. Sealed cell-DSC (SC-DSC) measurements for some azoles have been conducted and heats of reaction obtained by DSC have reflected the calculated  $\Delta H_f^\circ$  [112]. By combining heats of sublimation obtained by the additivity rule with  $\Delta H_f^\circ$  in the gas phase, which was obtained by using Parametric Method 3 (PM3),  $\Delta H_f^\circ$  of azoles in the solid phase have been estimated to within about  $\pm 10$  kcal/mol of observed values.

## 6 Pyrrole and Pyrrolidine

### 6.1 Pyrrole

Pyrrole (also called pyrrol),  $C_4H_5N$ , CAS RN [109-97-7], is a colorless, combustible fluid. It has a freezing point of m.p. 249 K =  $-24^\circ\text{C}$ , a boiling point of b.p. 403 K =  $130^\circ\text{C}$ , and a density of  $\rho = 0.9691\text{ g/cm}^3$  (Table 5). It discolors quickly when exposed to air, where it turns yellow and polymerizes to a brown resin. It is very sensitive to acids which turn it into a mix of red-colored polymers. The name is derived from its red discoloration. It has no value as a rocket propellant. Each of us carries pyrrole derivatives in our blood, as do the trees (in their leaves). Hemoglobin and chlorophyll are pyrrole derivatives [113]. The perhydrogenated pyrrole is pyrrolidine. Some energetic compounds are derived from it.

Pyrrole

Pyrrolidine

Pyrrole has a very low basicity compared to aliphatic amines. The decreased basicity is attributed to the delocalization of the lone pair of electrons of the nitrogen atom in the aromatic ring. Pyrrole is a very weak base with a  $pK$  of about  $-4$ . Pyrrole belongs to the heterocyclic compounds but its chemical behavior, evidenced by the ease of polymerization in the presence of traces of acids, is more that of a diene than that of an aromatic heterocyclic compound. The tendency toward resin formation makes it difficult to use pyrrole as a rocket fuel.

The addition of hydrazine is supposed to prevent resin formation by either pyrrole or *N*-methylpyrrole [114]. Similarly, the addition of hydrazine is supposed to reduce the resin formation during storage of furfuryl alcohol. Pyrrole stabilized by the addition of 3% hydrazine was reported to have a substantially reduced rate of resin formation, forming only 9.2 mg resin per 100 mL pyrrole within 60 d at 323 K ( $+60^\circ\text{C}$ ) compared to 418 mg resin formed in an untreated control sample. A parallel test with *N*-methyl pyrrole showed that the resin formation within 60 d was reduced from 471 to 17.8 mg by adding 3% hydrazine. The hydrazine addition not only improved the storability but also improved the ignition delay in a hypergolic bipropellant rocket engine. The phase diagram of the binary system pyrrole/hydrazine has two eutectic points: one at 11%  $\text{N}_2\text{H}_4$  melting at 233 K ( $-40^\circ\text{C}$ ) and the other at 49%  $\text{N}_2\text{H}_4$  melting at 236 K ( $-37^\circ\text{C}$ ).

Another patent describes fuel mixtures from pyrrole and ethylene imine which were already mentioned earlier in the ethylene imine chapter [22]. The suggested mixture ratios range from 10 to 97 vol.-% pyrrole and 13 to 19 vol.-% ethylene imine. A mixture of 80% pyrrole and 20% ethylene imine has a melting point of 223 K ( $-50^\circ\text{C}$ ) and has an ignition delay of only 7 ms with WFNA at 297 K ( $24^\circ\text{C}$ ) and an ignition delay of 11 ms at 233 K ( $-40^\circ\text{C}$ ).

**Table 5:** Physical properties of pyrrole.

| Property                                              | SI units                                   | Non-SI units                                       | References |
|-------------------------------------------------------|--------------------------------------------|----------------------------------------------------|------------|
| Molar mass                                            | 67.0892 g/mol                              | 14.906 mol/kg                                      | [14]       |
| Density                                               | 967 kg/m <sup>3</sup>                      | 0.967 g/cm <sup>3</sup>                            |            |

| Enthalpy of formation, liquid                         | $+63.1 \pm 0.4$ kJ/mol                     | +15.08 kcal/mol                                    | [14]       |
| Heat of evaporation, at normal boiling point (n.b.p.) | 38.75 kJ/mol                               | 9.26 kcal/mol                                      | [14]       |
| Heat of fusion, at 250 K                              | 7.9078 kJ/mol                              | 1.89 kcal/mol                                      | [14]       |

Pyrrole, pyrrolidine, and alkylpyrroles, by themselves or in mixtures with mercaptans, were patented as hypergolic fuels [115]. Nitropyrroles, nitropyrazoles, and nitroimidazoles are intermediates in the synthesis of other energetic compounds. 2-Nitropyrrole melts at 337–338 K (64–65 °C) and 3-nitro pyrrole melts at 373–374 K (100–101 °C) [116]. A study of the kinetics of thermal decomposition of pyrrole nitro derivatives with activation energies in the 35–57 kcal/mol range suggested that the decomposition of 2-nitro and 2,5-dinitropyrroles follows a molecular mechanism [117]. The decomposition of nitropyrroles substituted at the heterocyclic ring nitrogen atom follows a radical mechanism. The thermal stability of the pyrrole nitro derivatives increased on carrying the nitro group from the  $\alpha$  to the  $\beta$  position and rose when the NH group hydrogen was replaced by a methyl group.

## 6.2 Pyrrolidine

The fully hydrogenated pyrrole is pyrrolidine, also known as tetrahydropyrrole, azolidine, tetramethylene imine,  $C_4H_9N$ , CAS RN [123-75-1], molecular mass 71.121 g/mol, m.p. 213 K = –60 °C, b.p. 361 K = 88 °C,  $\rho$  = 0.8520 g/cm<sup>3</sup>. It is a fishy-smelling liquid, miscible with water and a strong base that forms stable salts with a range of mineral acids. There are no known uses of pyrrolidine as rocket fuel. Pyrrolidinium salts have been evaluated as ionic liquids.

### 6.2.1 Pyrrolidinium Salts

Pyrrolidinium nitrate,  $C_4H_{10}N_2O_3$ , CAS RN [129228-91-7],  $M$  = 134.13, is a low-melting IL. The melting point of pyrrolidinium nitrate is 258 K (–15 °C) and its freezing point is 246 K (–27 °C) [118]. Decomposition in a DSC started at 431 K (158 °C). The heat capacity at room temperature is 228 J mol<sup>–1</sup> K<sup>–1</sup>, the refractive index is 1.3955, and the density is 1.1675 g/cm<sup>3</sup> [119]. Density, electrical conductivity, and viscosity of pyrrolidinium nitrate (including in mixtures with inert diluents) were determined as being between 283 and 353 K [120]. The data are summarized in Table 6.

A batch of the protic IL pyrrolidinium nitrate exploded during drying under reduced pressure at 383 K (110 °C) using a rotary evaporator with a silicone oil bath [121]. Therefore, caution is necessary when working with any amine nitrate or perchlorate.

The heat of combustion of 1-butyl-1-methylpyrrolidinium dicyanamidate,  $[C_4H_8N(CH_3)C_4H_9]^+[N(CN)_2]^-$ ,  $C_{11}H_{20}N_4$ , CAS RN [370865-80-8] is  $7244.8 \pm 2.3$  kJ/mol, and the standard molar enthalpy of formation  $\Delta H_f^{298}$  (L) is  $+57.9 \pm 2.8$  kJ/mol and  $\Delta H_{melt}$  is  $161.0 \pm 2.0$  kJ/mol [122].

**Table 6:** Physical properties of pyrrolidinium nitrate.

| Temperature<br>K | Density<br>kg/m <sup>3</sup> | Viscosity<br>Pa s |
|------------------|------------------------------|-------------------|
| 283.15           | 1235 ± 2.8                   | 0.0589 ± 0.0059   |

Data source: [120].

## 7 Imidazoles and Pyrazoles

Imidazole (1*H*-imidazole, 1,3-diazole, 1,3-diazacyclopentene, glyoxaline (archaic), 1,3-diazacyclopenta-2,4-diene, C<sub>3</sub>H<sub>4</sub>N<sub>2</sub>, CAS RN [288-32-4]) is a stable heterocyclic amine. It forms colorless crystals (m.p. 363–364 K = 90–91 °C, b.p. 530 K = 257 °C,  $\rho = 1.030 \text{ g/cm}^3$ ,  $\Delta H_{298}^f(\text{S}) = +58.5 \text{ kJ/mol}$ ) and is soluble in water or alcohol. It is a weak base. Imidazole is used as an intermediate for the synthesis of many pharmaceutical drugs [123]. Imidazole and its hydrogenated members (imidazoline) are naturally occurring as building blocks in amino acids (histidine, histamine), peptides, and alkaloids. Imidazole itself is not useful as a rocket propellant. The interest in imidazole(s) as a rocket propellant ingredient stems mostly from the low melting point of the imidazolium salts, which places them into the category of “ionic liquids.” The most commonly shown structural formula is 1*H*-1,3-imidazole,

Imidazole

although compounds derived from other imidazoles (2*H*-imidazole, 4*H*-imidazole) are known. In searching for the ideal ionic liquid, the effect of substitution on the heterocyclic ring on the physical properties of the resulting salts has been thoroughly investigated.

Pyrazole, also known as 1*H*-pyrazole, 1,2-diazole, 1,2-diazacyclopentene, C<sub>3</sub>H<sub>4</sub>N<sub>2</sub>, CAS RN [288-13-1], is a stable heterocyclic amine and an isomer of imidazole. It forms soft, wax-like crystals that melt at 339–343 K = 66–70 °C and boil at 459–461 K = 186–

188°C. Pyrazole is the parent compound of a large number of energetic substances which are created by attaching explosophoric groups to the heterocyclic ring.

Pyrazole

Using a method first developed by von Pechmann in 1898, it was found that pyrazole can be synthesized from acetylene and diazomethane [124].

An easier method for the production of pyrazoles is the reaction of  $\alpha,\beta$ -unsaturated aldehydes with hydrazine and subsequent dehydrogenation:

## 7.1 Mono-Substituted Imidazoles

### 7.1.1 Nitroimidazole

The antibiotic azomycin is 2-nitroimidazole, which has many other uses in medical imaging. Depending on the strength of the nitrating agent and the operating conditions, the nitration of imidazole will yield mono-, di-, or tri-nitroimidazole [125].

The molecular structure and bond energies in nitroimidazoles, polynitroimidazoles, and their methyl derivatives were investigated using DFT methods [126]. The homolytic BDE corresponding to  $\text{—NO}_2$  group removal from carbon or nitrogen sites on the imidazole ring was calculated and the weakest bond was determined. A correlation was developed between impact sensitivity and the ratio (BDE/ $E$ ) of the weakest bond BDE to the total energy  $E$ . If one extrapolates this relationship, one can predict the impact sensitivities for compounds where experiments are not available. It was found that most of the nitroimidazoles were insensitive towards impact stimuli, with their 50% point being larger than 60 cm. HOFs for 21 nitroimidazoles at 298 K

in the gas phase were calculated using isodesmic work reactions. The calculated BDEs and HOFs consistently indicated that C-nitro-substituted imidazoles were more stable than the corresponding *N*-substituted ones. The introduction of methyl on C increased the stability whereas methyl groups attached to the N atom decreased the stability.

An *N*-functionalized strategy, including *N*-amination and *N*-trinitroethylamination, was utilized for the synthesis of nitroimidazole-based energetic materials, leading to a family of highly insensitive energetic *N*-aminonitroimidazoles and oxygen-rich *N*-trinitroethylaminonitroimidazoles with good safety properties [127]. The materials were characterized by IR,  $^1\text{H}$ , and  $^{13}\text{C}$  NMR, elemental analysis, and XRD. *N*-trinitroethylaminoimidazoles have favorable densities (1.75–1.84 g/cm<sup>3</sup>), good detonation properties ( $P_{\text{det}}$  27.6–35.9 GPa;  $v_{\text{det}}$  7815–8659 m/s), and moderate thermal stabilities (409–445 K = 136–172°C). These properties are better than those of some known energetic compounds, such as TNT or TATB.

4-Nitroimidazole,  $\text{C}_3\text{H}_3\text{N}_3\text{O}_2$ , molecular mass 113.07 g/mol, CAS RN [3034-38-6], melts at 576 K (303°C) (dec.) and is available commercially. It can be used as a building block for other energetic chemicals.

## 7.2 Di-Substituted Imidazoles

### 7.2.1 2,4-Dinitroimidazole

2,4-Dinitroimidazole; 1*H*-imidazole, 2,4-dinitro-; 2,4-DNI,  $\text{C}_2\text{H}_2\text{N}_4\text{O}_4$ , CAS RN [5213-49-0],  $M = 146.06$  g/mol, has a melting point of 537–540 K (264–267°C) and has moderate performance as an explosive that is expected to be 60% greater than TNT. However, it is less shock sensitive.

2,4-Dinitroimidazole

2,4-Dinitroimidazole (2,4-DNI) was synthesized by thermal rearrangement of 1,4-dinitroimidazole. 2,4-DNI is of interest mostly as an explosive where its performance is expected to be 60% better than TNT, however, it does not have any advantages as a rocket propellant [128]. The specific impulse is below that of HMX or TNAZ. It is also used as an intermediate in the synthesis of antibacterial pharmaceutical

drugs. 2,4-DNI crystallized in the orthorhombic space group, *Pbca* (with unit-cell dimensions  $a = 10.127(2) \text{ \AA}$ ,  $b = 18.497(2) \text{ \AA}$ ,  $c = 6.3337(2) \text{ \AA}$  and  $Z = 8$ ) and has an XRD density of  $1.770 \text{ g/cm}^3$  [129, 130].

Imidazole derivatives with more than two nitro groups are expected to be potential energetic ingredients for insensitive explosive or propellant formulations [131, 132]. The shock sensitivity of pressed solid 2,4-DNI was determined [133]. At an initial shock pressure of 2 GPa, several microseconds were required before any exothermic reaction was observed. At 4 GPa, 2,4-DNI reacted more rapidly but did not transition to detonation at the 12 mm deep gauge position. At 6 GPa, detonation occurred in less than 6 mm of shock propagation. Thus, 2,4-DNI is more shock sensitive than TATB-based explosives but is considerably less shock sensitive than HMX-based explosives.

The crystal structure of an isomeric dinitroimidazole, 4,5-dinitroimidazole was determined and compared to those of the 1,4- and 2,4-isomers [134]. The crystal structure of 4,5-dinitroimidazole was monoclinic, space group *P2<sub>1</sub>/n*,  $a = 11.5360$ ,  $b = 9.07$ ,  $c = 11.822$ ,  $\rho = 1.781 \text{ g/cm}^3$ . Both 4,5-dinitroimidazole and 5-nitrotetrazole, with electron-withdrawing nitro-substituents on the ring, are strong NH acids ( $\text{p}K_a = 0.8$  for 5-nitro-tetrazole).

Nitroimidazoles are amphoteric and can form salts with strong acids or strong bases. The molecular structure can be modeled to predict proton affinity. The protonation and deprotonation energies for all the nitro substituted imidazoles were computed [135]. This is a measure of the acid/base strengths of these compounds.

Thermal decomposition of 2,4-DNI was compared to that of HMX between 448 and 473 K (175 and 200 °C) using the STMBMS with a focus on the initial stages of the decomposition [136]. The early 2,4-DNI thermal decomposition is characterized by an initial decomposition, an apparent induction period, then an initial acceleratory period. The main gaseous products are NO, CO<sub>2</sub>, HNCO, H<sub>2</sub>O, N<sub>2</sub>, CO, HCN, and C<sub>2</sub>N<sub>2</sub>. The presence of adsorbed and occluded H<sub>2</sub>O is a possible cause for the early decomposition. The solid-phase thermal decomposition of 2,4-DNI was studied utilizing STMBMS between 473 and 520 K (200 and 247 °C) [137–140]. Arrhenius parameters for the induction period are  $E_a = 46.9 \pm 0.7 \text{ kcal/mol}$  and  $\log(A) = 16.3 \pm 0.3$ . The pyrolysis products were identified using perdeuterated and <sup>15</sup>N-labeled isotopomers. The products consisted of low molecular-weight gases and a thermally stable solid residue that was polyurea- and polycarbamate-like in nature.

A study of the thermal decomposition of 2,4-dinitroimidazole and 1,4-dinitroimidazole provided experimental evidence of an N–NO<sub>2</sub> bond scission reaction step in the nitramine functional group of 1,4-DNI under high heating rates [141]. No corresponding mechanism was found in 2,4-DNI, which has no N–N bonds and no nitramine functional groups. Under slow heating conditions, the main reaction channel was the conversion of 1,4-DNI to 2,4-DNI and subsequent decomposition to form CO<sub>2</sub>, N<sub>2</sub>O, NO, HCN, and other minor products. Attempts to isolate the initial reaction products were unsuccessful. There was no evidence for the formation of NO

at any stage in the reaction of 2,4-DNI. Therefore, C—NO bond scission is unlikely to play a major role in the decomposition mechanism of 2,4-DNI.

A physicochemical and mathematical model of the decomposition of 2,4-DNI was developed and applied to the experimental results [142]. The first generation of this model revealed differences between theoretical and experimental data collected under different conditions.

The thermal stability of 2,4-DNI and that of six other explosives was measured by using STMBMS. The results were compared to develop a kinetic model and identify the rate-determining steps [84]. The crystal structure of 2,4-DNI has been resolved by using neutron scattering spectroscopy and compared to a predicted structure calculated by using DFT methods [143].

The synthesis of 2,4-dinitroimidazole (2,4-DNI) by rearrangement of 1,4-dinitroimidazole (1,4-DNI) can be achieved by microwave heating instead of conventional heating [144]. This method improved the yield of the product and shortened the reaction time from 4–50 h to 10 min with the yield of 2,4-DNI up to 95% with a melting point of 538–541 K (265–268 °C) (decomposition). Direct nitration of imidazole with a mixture of concentrated nitric acid and concentrated sulfuric acid gives 4,5-dinitroimidazole, which can be converted to its ammonium salt [145].

Amino-2,4-dinitroimidazole (ADNI) was synthesized by amination of 2,4-dinitroimidazole with 2,4,6-trimethylbenzenesulfonic hydroxylamine in a total yield of 57.8% [146]. The structure of ADNI was characterized by IR, <sup>1</sup>H NMR, LC-MS, and single-crystal XRD. Results showed that ADNI belongs to an orthorhombic system, space group *Pca*2<sub>1</sub> with *a* = 10.0626(14) Å, *b* = 55.684(8) Å, *c* = 11.5639(15) Å, *Z* = 4, *D*<sub>c</sub> = 1.774 g/cm<sup>3</sup>. DSC test results revealed that ADNI has good thermal stability.

2,4-Dinitroimidazole was synthesized by nitrating 2-nitroimidazole and a thermal rearrangement of 1,4-dinitroimidazole and characterized by thermal decomposition, crystallization characteristics, explosion performance, friction sensitivity, and impact sensitivity [147]. 2,4-Dinitroimidazole was tested as an explosive in comparison to LAX112 and TNAZ [104].

The impact sensitivity of polynitroimidazoles, polynitropyrazoles, and similar nitroheterocyclic compounds can be predicted by interpolating between known data and applying structural adjustment factors [148, 149].

### 7.2.2 2-Azido-4-nitroimidazole

2-Azido-4-nitroimidazole and several of its derivatives have been synthesized for energetic material applications [150]. The calculated densities of the compounds ranged between 1.71 and 1.92 g/cm<sup>3</sup>. The calculated detonation pressures for these derivatives were in the range from 25.17 to 32.62 GPa and the detonation velocities were in the range from 7.65 to 8.55 km/s.

2-Azido-4-nitroimidazole was synthesized using 2-amino-4-nitroimidazole or 2-azidoimidazole as raw materials with yields of 87 or 78%, respectively, and its

structure was confirmed by MS, IR, and  $^1\text{H}$  NMR [151]. The calculated detonation velocity and detonation pressures were 7.59 km/s and 24.39 GPa, respectively. 2-Azido-4-nitroimidazole is tautomeric and can act either as an acid or as a base. The structures of salts formed from nitrogen-rich bases and 2-azido-4-nitroimidazole were determined by IR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, and elemental analysis [152]. These salts exhibited high positive enthalpies of formation, high nitrogen content, and moderate detonation properties.

## 7.3 Tri-Substituted Imidazoles

### 7.3.1 1-Nitramino-2,4-dinitroimidazole

New energetic salts based on 1-nitramino-2,4-dinitroimidazole were synthesized and characterized by  $^1\text{H}$  and  $^{13}\text{C}$  NMR, IR spectroscopy, DSC, and elemental analyses [153]. The salts were found to have good physical and detonation properties. The crystal structure of guanidinium 1-nitramino-2,4-dinitroimidazolate was further confirmed by single-crystal XRD. The densities of the energetic salts ranged between 1.70 and 1.93  $\text{g}/\text{cm}^3$  as measured by a gas pycnometer. The detonation pressures and detonation velocities calculated by the EXPLO5 code ranged between 29.3–40.5 GPa and 8370–9209 m/s, respectively.

### 7.3.2 2,4,5-Trinitroimidazole

2,4,5-Trinitroimidazole, 2,4,5-trinitro-1*H*-imidazole,  $\text{C}_3\text{H}_2\text{N}_5\text{O}_6$ ,  $M = 203.070$  g/mol, CAS RN [24079-73-0], is an explosive energetic material with an acidic character. 2,4,5-Trinitroimidazolate (TNI) salts with “high-nitrogen” cations tend to be highly

hydrogen-bonded and have extremely positive enthalpies of formation ranging up to 616 kJ/mol [154]. The enthalpy of formation of 2,4,5-trinitroimidazole is +201 kJ/mol (+48.1 kcal/mol).

2,4,5-Trinitroimidazole

1-Methyl-2,4,5-trinitroimidazole can be synthesized with 1-methylimidazole as an initial material via a two-step nitration reaction [155]. Its structure was characterized by IR,  $^1\text{H}$  NMR, and elemental analysis.

#### 7.4 Tetra-Substituted Imidazoles

HOFs ( $\Delta H_f^\circ$ ) in the gas phase of substituted imidazole-based energetic materials were theoretically investigated by employing DFT and isodesmic reactions [156]. The BDEs corresponding to  $\text{NO}_2$ ,  $\text{NH}_2$ ,  $\text{CH}_3$ , and Cl removal from carbon or nitrogen positions of the azole ring were calculated. The substituent effect of electron-withdrawing ( $\text{NO}_2$ , Cl) and electron-donating ( $\text{NH}_2$ ,  $\text{CH}_3$ ) groups affects the  $\Delta H_f^\circ$ , BDE, stability, and acidity/basicity of these molecules. One of the most promising energetic compounds, which have potentially good energetic performance and low sensitivity, was 1-amino-2,4,5-trinitroimidazole.

#### 7.5 Other Nitroimidazoles

Various nitroimidazole derivatives including 2,4-dinitroimidazole, 4,5-dinitroimidazole, 2,4,5-trinitroimidazole, 1,2,4,5-tetranitroimidazole, and 1-methyl-2,4,5-trinitroimidazole have been investigated experimentally and theoretically [157]. The structure of 1,2,4,5-tetranitroimidazole has been investigated theoretically by using various levels of theories [158].

4,4',5,5'-Tetranitro-2,2'-bi-1*H*-imidazole (TNBI) has been synthesized by treating 2,2'-bi-1*H*-imidazole with an excess of sodium nitrate. Unfortunately, despite their importance in the development of new energetic materials, few studies are found in the literature concerning the thermodynamic properties of the imidazole derivatives in detail. The enthalpies of formation have been calculated for several imidazole deriva-

tives, with a focus on a particular group of picryl-substituted imidazoles using DFT methods [159]. The computed condensed phase HOFs are listed in Table 7.

**Table 7:** Predicted condensed phase HOFs of imidazole derivatives.

| Compound name                 | Gross formula     | $\Delta H_f$ condensed |          |
|-------------------------------|-------------------|------------------------|----------|
|                               |                   | kJ/mol                 | kcal/mol |
| 1-Picrylimidazole             | $C_9H_5N_5O_6$    | +296                   | +70.8    |
| 2-Nitro-1-picrylimidazole     | $C_9H_4N_6O_8$    | +295                   | +70.4    |
| 4-Nitro-1-picrylimidazole     | $C_9H_4N_6O_8$    | +295                   | +70.4    |
| 2,4-Nitro-1-picrylimidazole   | $C_9H_3N_7O_{10}$ | +293                   | +70.0    |
| 2,4-Dinitroimidazole          | $C_3H_2N_4O_4$    | +247                   | +59.0    |
| 2,4,5-Trinitroimidazole       | $C_3HN_5O_6$      | +245                   | +58.6    |
| 4,4',5,5'-Tetranitroimidazole | $C_6H_2N_8O_8$    | +558                   | +133.3   |

Data source: [159].

Table 8 is a summary of the predicted heat of detonation, molar volume, density, detonation velocity  $D$ , and Chapman-Jouguet ( $C-J$ ) pressure  $P$  of substituted nitro-imidazole compounds. Reviewing the direct imidazole and 1-picrylimidazole derivatives, it is noted that the values of  $D$  and  $P$  gradually increase when the number of  $-NO_2$  groups increases.

**Table 8:** Predicted densities and detonation properties of substituted nitroimidazole compounds.

| Compound                      | $Q$   | $V$                  | $\rho$            | $D$   | $P$   |
|-------------------------------|-------|----------------------|-------------------|-------|-------|
|                               | kJ/g  | cm <sup>3</sup> /mol | g/cm <sup>3</sup> | km/s  | GPa   |
| 1-Picrylimidazole             | 5.466 | 147.22               | 1.90              | 10.78 | 53.64 |

| 4,4',5,5'-Tetranitroimidazole | 6.600 | 169.82               | 1.85              | 12.28 | 68.02 |

Data source: [159].

The thermal stability of four imidazole-based energetic molecules (1,4-dinitroimidazole, 2,4-dinitroimidazole, 1-methyl-2,4-dinitroimidazole, and 1-methyl-2,4,5-trinitroimidazole)

was studied both experimentally and theoretically [160]. Different from PETN, HMX, and RDX, the thermal dissociation process (ground electronic state decomposition from the Franck-Condon equilibrium point) of multi-nitroimidazoles was predicted to be a competition between  $\text{NO}_2$  elimination and nitro-nitrite isomerization followed by  $\text{NO}$  elimination for all multi-nitroimidazoles except 1,4-dinitroimidazole. In the latter instance,  $\text{N}-\text{NO}_2$  homolysis became the dominant decomposition channel on the ground electronic state, as found for HMX and RDX. Energetic materials with  $\text{C}-\text{NO}_2$  are usually more thermally stable and impact/shock insensitive than other energetic materials are with  $\text{N}-\text{NO}_2$  and  $\text{O}-\text{NO}_2$  moieties. The imidazole aromatic ring also plays an important role in improving the stability of these energetic materials. Thus, multi-nitroimidazoles energetic materials can be of significant potential for both civilian and military applications.

## 7.6 Imidazolium Salts

The nomenclature for these compounds is not very strict. They could be called imidazole salts or imidazolium salts. After the imidazole is protonated, the location of the positive charge cannot be fixed and a resonance process (which is very stable like a benzene ring) distributes the positive charge over the entire ring structure.

This enhances the stability of the ion(s). The physical properties of imidazolium salts are summarized in Table 9. The picrate salts melt at substantially higher temperatures than the nitrate salts and they are not considered ionic liquids. An excellent summary review of azole (azolium, azolate, imidazole, triazole, and tetrazole) salts with 387 references is provided in [109].

**Table 9:** Physical properties of imidazolium salts.

| Compound name                                        | Glass point |     | Onset of decomposition |      | Melting point |      | Density at 298 K<br>g/cm <sup>3</sup> | Enthalpy of formation <sup>a</sup> |          | References |
|------------------------------------------------------|-------------|-----|------------------------|------|---------------|------|---------------------------------------|------------------------------------|----------|------------|
|                                                      | K           | °C  | K                      | °C   | K             | °C   |                                       | kJ/mol                             | kcal/mol |            |

<sup>a</sup> Estimated for solid phase.

Several imidazolium-based ionic liquid azides with saturated and unsaturated side chains were prepared and their physical and structural properties were investigated [162, 165]. The hypergolic ignition reactivity of these new and some previously reported ionic liquid azides with N<sub>2</sub>O<sub>4</sub> and inhibited red fuming nitric acid (IRFNA) was studied. With IRFNA and N<sub>2</sub>O<sub>4</sub>, all compounds reacted vigorously with copious production of red fumes but without ignition. The initial heat release during these reactions did not result in hypergolic ignition of the material under the tested conditions.

Thermophysical properties of imidazole-derivative 13 ILs were determined by using DSC, but only one of the ILs investigated would be of interest as a rocket propellant: 1-*n*-butyl-3-methylimidazolium dicyanamidate, CAS RN [44824-52-1]. This is a potential fuel for bipropellant engines [164]. Its density at 297 K (24 °C) is 1.0580 g/cm<sup>3</sup> and at 355.8 K (82.7 °C) is 1.0258 g/cm<sup>3</sup>. It has a glass transition temperature of 183 K (−90 °C) and a melting point of 267 K (−6 °C). The heat capacity at 298 K is 364.6 J mol<sup>−1</sup> K<sup>−1</sup> and the heat capacity function is  $C_p = 0.197T + 305.81$  J mol<sup>−1</sup> K<sup>−1</sup>.

Atomistic molecular dynamics (MDs) simulations were performed on the ionic liquids 1-butyl-3-methylimidazolium azide [bmim][N<sub>3</sub>], 1-butyl-2,3-dimethylimidazolium azide [bmmim][N<sub>3</sub>], and 1-butylnyl-3-methylimidazolium azide [bumim][N<sub>3</sub>]

[166]. Good agreement between the experimentally determined and simulated crystal structure of [bumim][N<sub>3</sub>] as well as the liquid-state density and ionic conductivity of [bmmim][N<sub>3</sub>] was achieved. Methylation of bmim (yielding bmmim) resulted in dramatic changes in the ion structuring within the liquid and slowing of ion motion. Conversely, replacing the butyl group of bmim with the smaller 2-butylnyl group resulted in an increase of ion dynamics.

There has been a great deal of interest in energetic materials based on ionic salts containing heterocyclic rings derived from 1*H*-imidazole, 1*H*-1,2,4-triazole, 1*H*-1,2,3-triazole, and 1*H*-tetrazole, which all have a high nitrogen content. These materials derive their energetic qualities from their high enthalpies of formation ( $\Delta H_f^\circ$ 's) due to the large number of C—N and N—N bonds and the more compact nature of the heterocyclic ring systems, which add density to the materials. The crystalline enthalpies of formation increase from 58.6 to 109.2 to 237 kJ/mol (14.0 to 26.1 to 56.7 kcal/mol) for 1*H*-imidazole, 1*H*-1,2,4-triazole, and 1*H*-tetrazole, respectively. The following paper [167] is referenced at all three locations at imidazolium, triazolium, and tetrazolium salts. Here is the first location where it is referenced and this is where we discuss it in detail. Reliable  $\Delta H_f^\circ$ 's for energetic precursor molecules and ions were used as a starting point for a computational approach to the prediction of the HOFs of solid-state energetic salts from electronic structure and volume-based thermodynamic (VBT) calculations [167]. The  $\Delta H_f^\circ$ 's of more complex energetics species such as substituted imidazole, 1,2,4-triazole, and tetrazole molecules and ions containing amino, azido, and nitro (including methyl) substituents were calculated using an isodesmic approach. Based on comparisons to experimental data for neutral analogues, this isodesmic approach was accurate to <3 kcal/mol for the predicted cation and anion  $\Delta H_f^\circ$ 's. The  $\Delta H_f^\circ$ 's of the energetic salts in the solid state were derived from lattice energy ( $U_L$ ) calculations using a VBT approach. Improved values for the  $\alpha$  and  $\beta$  parameters of 19.9 (kcal nm)/mol and 157 kJ/mol (37.6 kcal/mol) for the  $U_L$  equation were obtained on the basis of comparisons to experimental  $U_L$ 's for a series of 23 salts containing ammonium, alkylammonium, and hydrazinium cations. The total volumes were adjusted to account for differences between predicted and experimental total volumes due to the different shapes of the ions (flat vs. spherical). The predicted  $\Delta H_f^\circ$ 's of the energetic salts were estimated to have error bars of 25–29 kJ/mol (6–7 kcal/mol), on the basis of comparisons to established experimental  $\Delta H_f^\circ$ 's of a subset of the salts studied. Energetic salts with the highest positive  $\Delta H_f^\circ$ 's were predicted for azido-containing cations, coupled with heterocyclic anions containing nitro substituents. The substitution of functional groups on carbon versus nitrogen atoms of the heterocyclic cations had interesting stabilization and destabilization effects.

Using the experimental (or calculated) values for densities, a combination of theoretical and empirical calculations was used to predict the HOFs of energetic salts [168]. The HOFs of cations and anions and the lattice energies of 119 energetic salts were cal-

culated separately based on Born-Haber energy cycles. The HOFs coupled with densities can be used further for predicting the detonation pressures and velocities and specific impulses of energetic salts. This is a straightforward and inexpensive route to screen large numbers of energetic salts.

One of the anions which imidazolium cations can be combined with is *N,N'*-dinitrourea. The crystal structure and vibrational spectrum of imidazolium *N,N'*-dinitrourea were investigated in detail [169]. *In-situ* IR analysis, mass spectral fragmentation, and bond dissociation enthalpy calculations revealed that the initial decomposition step of imidazolium *N,N'*-dinitrourea was the breakage of the N–N bond in the anion. The *in-situ* IR of gaseous phase products and mass spectral fragmentation indicated that the main final products of decomposition were N<sub>2</sub>O and imidazole.

A series of dicationic fluoro-substituted alkylimidazolium salts have been synthesized and characterized [170]. The properties of these salts, including density, transition and decomposition temperatures, indicated that their performance was strongly dependent on the positions of the fluoro substituents, the number of carbon atoms in the alkyl group, and the anion they were partnered with.

### 7.6.1 Imidazolium Nitrate

Imidazolium nitrate, C<sub>3</sub>H<sub>5</sub>N<sub>3</sub>O<sub>3</sub>, is a potential rocket propellant ingredient. In addition to unsubstituted imidazolium nitrate, the nitrates of mono- and di-methyl substituted imidazoles have been characterized [161]. They have somewhat higher melting points, but the melting points are still below 373 K (100 °C). Therefore, they fall under the category of ionic liquids.

The synthesis of ten *N*-alkyl-*N*-cyanoalkyl-functionalized imidazolium (*N*-methyl- and *N*-butyl-*N*-((CH<sub>2</sub>)<sub>*n*</sub>CN)imidazolium; *n* = 1–4) nitrate and eleven *N*-alkyl-*N*-cyanoalkyl-functionalized imidazolium (*N*-methyl-*N*-((CH<sub>2</sub>)<sub>*n*</sub>CN)imidazolium; *n* = 1–6, *N*-(2-cyanoethyl)-*N*-((CH<sub>2</sub>)<sub>*n*</sub>CN)imidazolium; *n* = 1, 3–6) dicyanamidate salts was achieved via *N*-alkylation of substituted imidazoles with haloalkylnitriles followed by anion exchange [171]. Based on their observed melting points, all dicyanamide salts and all but one nitrate salt (1-cyanomethyl-3-methylimidazolium nitrate) had melting points of <373 K (<100 °C). DSC data indicated that melting points can be decreased by increasing the *N*-alkyl or *N*-cyanoalkyl chain length or by exchanging with the dicyanamide anion, which produced the lowest melting points in comparison to analogous halide or nitrate salts. Thermogravimetric analyses indicated that thermal stability increased for longer *N*-cyanoalkyl substituent lengths. However, it decreased significantly for nitrates and more so for dicyanamides bearing short-chain *N*-cyanoalkyl substituents [e.g., *N*-cyanomethyl, *N*-(1-cyanoethyl), and *N*-(2-cyanoethyl)] in comparison to halide precursors.

### 7.6.2 Imidazolium Perchlorate

Imidazole•imidazolium perchlorate, which is imidazolium perchlorate with an additional imidazole molecule attached, crystallizes as colorless plates that are exceedingly sensitive to moisture. XRD spectra indicated that the crystal lattice is monoclinic,  $a = 5.0994(3) \text{ \AA}$ ,  $b = 8.7333(5) \text{ \AA}$ ,  $c = 11.8228(5) \text{ \AA}$ ,  $\beta = 98.691(5)^\circ$ ,  $Z = 2$ ,  $\rho_{\text{XRD}} = 1.51 \text{ g/cm}^3$ , space group  $P2_1$ . The proton is shared between the two rings by hydrogen bonding with a hydrogen bond length of  $2.73 \text{ \AA}$  [172]. Imidazolium perchlorate is a ferroelectric substance.

Structural, dielectric, and optical properties of the imidazolium perchlorate crystal have been studied via XRD, dielectric, and birefringence measurements [173]. On cooling, structural phase transitions occurring at  $373 \text{ K}$  ( $T_{c1}$ ) and  $210 \text{ K}$  ( $T_{c2}$ ) are of second and first order, respectively. The crystal is destroyed below  $T_{c2}$  by a large structure deformation.

Imidazolium perchlorate has been synthesized and studied over a wide range of temperatures by DSC, XRD, proton NMR, optical observation, and dielectric spectroscopy [174]. Polymorphic solid-solid phase transitions were taking place at  $487$ ,  $373$ , and  $247 \text{ K}$ . The crystal structure at  $298 \text{ K}$  has been determined as trigonal, space group  $R3m$ ,  $Z = 1$  with  $a = 5.484(1) \text{ \AA}$  and  $\alpha = 95.18(2)^\circ$ . At  $385 \text{ K}$  the crystal structure remained trigonal, space group  $R\bar{3}m$ ,  $a = 5.554(1) \text{ \AA}$  and  $\alpha = 95.30(2)^\circ$ . Dielectric measurements revealed the crystal as a new ferroelectric compound with a Curie point of  $373 \text{ K}$ .

Precise measurements of specific heat changes have been performed for imidazolium perchlorate crystals using an AC calorimeter [175]. Phase transitions took place at about  $373$  and  $219 \text{ K}$ , with the continuous second-order phase transition at  $373 \text{ K}$  going to the ferroelectric phase. Excess enthalpy,  $\Delta H$ , and the excess entropy,  $\Delta S$ , of the continuous transition were estimated.

### 7.6.3 Other Imidazolium Salts

Imidazolium picrate  $[\text{C}_3\text{N}_2\text{H}_5^+][\text{C}_6\text{N}_3\text{O}_7\text{H}_2^-]$  was prepared by mixing an imidazole ethanol solution and picric acid ethanol solution [176]. Single crystals suitable for XRD measurement were cultured at room temperature. The crystal is a rhombic system, space group  $Pbca$  with crystal parameters of  $a = 0.8950 \text{ nm}$ ,  $b = 1.3474(3) \text{ nm}$ ,  $c = 2.0164 \text{ nm}$ ,  $\alpha = \beta = \gamma = 90^\circ$ ,  $V = 2.4317(3) \text{ nm}^3$ ,  $D_c = 1.624 \text{ g/cm}^3$ ,  $Z = 8$ . A theoretical investigation of imidazolium picrate structure was carried out by computational chemistry methods and the atomic net charges and the electron population density were calculated.

### 7.6.4 Mono-Substituted Imidazolium and Imidazolate Salts

A computational approach to the prediction of the HOFs ( $\Delta H_f^\circ$ 's) of solid-state energetic salts from electronic structure and VBT calculations used as its starting point reliable  $\Delta H_f^\circ$ 's for energetic precursor molecules and ions [167, 177]. The  $\Delta H_f^\circ$ 's of more

Data source: [167].

complex energetic species such as substituted imidazole, 1,2,4-triazole, and tetrazole molecules and ions were calculated in this way and compared to experimental data (Table 10).

Based on comparisons to experimental data for neutral analogues, this isodesmic approach was accurate to <3 kcal/mol for the predicted cation and anion  $\Delta H_f^\circ$ . The  $\Delta H_f^\circ$  data of the energetic salts in the solid state were derived from lattice energy calculations using a valence bond theory approach. The predicted  $\Delta H_f^\circ$  of the energetic salts were estimated to have error bars of 25–29 kJ/mol (6–7 kcal/mol), based on comparisons to established experimental  $\Delta H_f^\circ$  of a subset of the salts studied. Energetic salts with the highest positive  $\Delta H_f^\circ$  were predicted for azido-containing cations, coupled with heterocyclic anions containing nitro substituents. The substitution of functional groups on carbon versus nitrogen atoms of the heterocyclic cations can have stabilizing or destabilizing effects.

The initial melting point analysis revealed that generally, due to the size and shape of the anion, the nitrate salts exhibited significantly lower melting points than their picrate equivalents [177, 178]. TGA of nitro-substituted and non-substituted protonated imidazolium salts revealed that thermal stabilities range from 343–473 K (70–200 °C), with picrate salts exhibiting higher stabilities (by 40 K = 40 °C) than nitrate salts. Disappointingly, however, the thermal stabilities of these protonated salts were significantly lower than those of alkylated derivatives.

Three organic imidazolium-based perchlorate salts ILs have been synthesized by simple, inexpensive, and non-hazardous methods, using ammonium perchlorate (AP) as the perchlorate source [179]. By selecting the appropriate cation, perchlorate can be incorporated into an ionic liquid which serves as its own electrolyte for the electrochemical reduction of the perchlorate anion, using an ionic liquid as both reagent

and electrolyte. This is a continuous perchlorate removal/remediation process for converting sometimes unwanted perchlorate to chloride. Instead of using  $\text{HClO}_4$  (which is dangerous when mixed with organics),  $\text{LiClO}_4$ , or  $\text{AgClO}_4$  (which has a higher cost) it is more economical to utilize AP (even recycled AP) in the synthesis of perchlorate-based ILs. Three potential routes to incorporate the perchlorate anion into potentially energetic 1-methylimidazolium, using AP as the perchlorate source, are: **(1)** the reaction of a neutral amine (1-methylimidazole) with AP in aqueous solution, resulting in the formation of a protonated imidazolium perchlorate and liberating ammonia gas; **(2)** decarboxylation of 1,3-dimethylimidazolium-2-carboxylate<sup>13</sup> by reaction with AP to form 1,3-dimethylimidazolium perchlorate,  $\text{NH}_3$ , and  $\text{CO}_2$ ; and **(3)** metathesis of 1-butyl-3-methylimidazolium chloride with AP in water, forming the insoluble 1-butyl-3-methylimidazolium perchlorate and water-soluble  $\text{NH}_4\text{Cl}$ .

A series of functionalized imidazolium and 1,2,4-triazolium salts with cyanomethyl, vinyl, and propargyl substituents coupled with energetic anions (such as perchlorate, nitrate, dicyanamidate, and dinitramidate) were prepared and characterized by NMR and IR spectroscopy and elemental analyses [180, 181]. Since some of these salts melt  $<373\text{ K}$  ( $<100^\circ\text{C}$ ), they can be classified as ionic liquids. Their densities ranged between 1.25 and  $1.76\text{ g/cm}^3$ . The standard enthalpies of formation of the salts were calculated and ranged from  $\Delta H^\circ_f = -56$  to  $+851\text{ kJ/mol}$ . Of all the salts synthesized, the dicyanamidates exhibited the highest positive HOFs but also the lowest densities.

The dinitromethanide  $(\text{NO}_2)_2\text{CH}^-$  anion proved to be a useful component of room temperature ILs with substituted imidazolium cations [182]. Delocalization of both the  $(\text{NO}_2)_2\text{CH}^-$  anion and dimethylimidazolium cation was found from single-crystal structure data. Their impact sensitivities were determined, and they were found to be insensitive ( $>40\text{ J}$ ).

Although the following paper deals only with ionic liquids with non-energetic anions, the insight gained about the thermal stability of the cations is useful for developing other (energetic) ionic liquids. The thermal decomposition of a series of imidazolium-type IL samples was studied using pyrolysis-gas chromatography at  $823\text{ K}$  ( $550^\circ\text{C}$ ) [183]. As for the imidazolium halides, haloalkanes and 1-alkylimidazoles corresponding to the alkyl substituents were mainly formed through the nucleophilic attacks of halide ions to the alkyl groups. This was followed by C—N bond cleavage along with a minor amount of alkenes. Meanwhile, in the case of the ionic liquids with  $\text{BF}_4$ ,  $\text{PF}_6$ , and  $\text{CF}_3\text{SO}_3$  anions, corresponding alkenes were predominantly produced along with 1-alkylimidazoles rather than haloalkanes. As for the samples with longer alkyl groups, the pyrolyzates reflecting the C—C bond scissions in the alkyl groups were also formed to some extent. Imidazole rings did not split under the experimental conditions at around  $823\text{ K}$  ( $550^\circ\text{C}$ ).

## 7.6.5 Di-Substituted Imidazolium and Imidazolate Salts

### 7.6.5.1 Di-Substituted Imidazolium Salts

The melting points of organic salts are influenced by the symmetry of the molecule, the flexibility of the alkyl or aryl substituents, and the accessibility of the charges. An interesting graph in the ionic liquids literature, which is provided in Figure 5, demonstrates the plot of the melting point of an ionic liquid as a function of structure modification [184]. This graph shows the tremendous effect of modest structural changes on physical properties. A similar trend is observed when the melting point is plotted versus the counter anion structure. This illustrates one of the greatest advantages of ionic liquids, their tunable physical properties.

**Figure 5:** Melting point versus alkyl chain length of 1-alkyl-3-methylimidazolium tetrafluoroborates. (Modified from [184] with permission obtained from Dr. Joshua Aronson, 30 June 2020.)

The influence of the substituents on both formation and thermal properties of ionic liquids, the salts of 1,3-dimethyl-4-nitroimidazolium, 1-ethyl-3-methyl-4-nitroimidazolium, 1,2,3-trimethyl-4-nitroimidazolium, 1,3-dimethyl-2-nitroimidazolium, and 1-ethyl-3-methyl-2-nitroimidazolium has been determined by DSC, TGA, and single-crystal XRD. It was shown that an electron-withdrawing nitro substituent can be successfully appended and has a similar influence on the melting behavior as that of corresponding methyl group substitution. In the solid state, the nitro group has a suggestive effect, beyond the steric contribution, on the crystal packing. Twelve 1,3-dialkylimidazolium salts containing strong electron-withdrawing groups (EWG) nitro- and cyano-functionalities directly appended to the cationic heterocyclic rings have been synthesized. However, the anions (methylsulfonate, triflate, bis(triflyl)-imides) were less suitable as energetic salts [185]. The goal was to develop synthetic

and predictive strategies for the introduction of energetic functions and components into ionic liquid systems, as well as to understand how to engineer low melting or specific activity ILs.

Twenty-eight energetic salts with tetramethyl-, tetraethyl-, and tetrabutylammonium and 1-butyl-3-methylimidazolium cations paired with 3,5-dinitro-1,2,4-triazolate, 4-nitro-1,2,3-triazolate, 2,4-dinitroimidazolate, 4,5-dinitroimidazolate, 4,5-dicyanoimidazolate, 4-nitroimidazolate, and tetrazolate anions have been prepared and characterized by using DSC, TGA, and single-crystal XRD in order to study the effects of cation and anion type on the physicochemical properties of the resulting crystalline salts or ionic liquids [186]. Ionic liquids (defined as having m.p.  $<373\text{ K} = <100^\circ\text{C}$ ) were obtained with all combinations of the 1-butyl-3-methylimidazolium cation ( $[\text{C4mim}]^+$ ) and the heterocyclic azolate anions studied. Ionic liquids were also obtained with several combinations of tetraethyl or tetrabutylammonium cations and the azolate anions. The  $[\text{C4mim}]^+$  azolates were liquids at room temperature where they exhibited wide liquid ranges and formed glasses on cooling. Glass-transition temperatures were in the range of 220 to 191 K ( $-53$  to  $-82^\circ\text{C}$ ), except for the 3,5-dinitro-1,2,4-triazolate salt with m.p.  $306\text{ K} = 33^\circ\text{C}$ .

Rapid-scan FTIR spectroscopy and TOF mass spectrometry were used to study the thermal decomposition of three imidazolium-based ionic liquids, with 1-ethyl-3-methyl-imidazolium (emim) as the cation and  $\text{NO}_3^-$ ,  $\text{Cl}^-$ , and  $\text{Br}^-$  as the anions at heating rates of  $2000\text{ K/s}$  and temperatures to  $435^\circ\text{C}$  in an ambient inert gas at 1 atm [187]. The evolution of gas-phase species indicated that the most probable sites for proton transfer and subsequent secondary reactions were primarily the methyl group and, secondarily, the ethyl group. The ring appeared to remain intact, as there was no evidence of the formation of HCN, imines, or related products. The nitrate group in  $[\text{emim}]\text{NO}_3$  served as a strong oxidizer and reacted strongly with the methyl/ethyl groups at elevated temperatures to produce combustion products.

The molar enthalpy of formation of the liquid 1-butyl-3-methylimidazolium dicyanamide was measured using a combustion calorimetry and found to be  $206.2 \pm 2.5\text{ kJ/mol}$ . The molar enthalpy of vaporization was obtained from the temperature dependence of the vapor pressure measured using the transpiration method and was found to be  $157.2 \pm 1.1\text{ kJ/mol}$  [188]. The enthalpy of formation of gaseous 1-butyl-3-methylimidazolium dicyanamide was  $363.4 \pm 2.7\text{ kJ/mol}$ .

Thirty-one salts were synthesized by pairing diverse cations (1-butyl-3-methylimidazolium, tetramethyl-, tetraethyl-, and tetrabutylammonium) with azolate anions (5-nitrobenzimidazolate, 5-nitrobenzotriazolate, 3,5-dinitro-1,2,4-triazolate, 2,4-dinitroimidazolate, 4-nitro-1,2,3-triazolate, 4,5-dinitroimidazolate, 4,5-dicyanoimidazolate, 4-nitroimidazolate, and tetrazolate) [189]. These salts were characterized by DSC, TGA, and single-crystal XRD. The azolates in general were surprisingly stable in the systems explored. Ionic liquids were obtained with all combinations of the 1-butyl-3-methylimidazolium cation and the heterocyclic azolate anions studied, and with several combinations of tetraethyl- or tetrabutylammonium cations and the

Data source: [191]

azolate anions. Favorable structure-property relationships were most often achieved when changing from 4- and 4,5-disubstituted anions to 3,5- and 2,4-disubstituted anions. The most promising anion for use in energetic ionic liquids (EILs) of those studied for this publication was 3,5-dinitro-1,2,4-triazolate. This is based on its contributions to the entire set of desired properties.

Thermal stability and thermal decomposition kinetics of 1-butyl-3-methylimidazolium dicyanamidate ([bmin<sup>+</sup>][N(CN)<sub>2</sub><sup>−</sup>]) were investigated using both isothermal and non-isothermal TGA under high pure nitrogen as carrier gas [190]. The long-term thermogravimetric studies revealed that the highest storage temperature should be 383 K = 110 °C. At this temperature [bmin<sup>+</sup>][N(CN)<sub>2</sub><sup>−</sup>] lost less than 10% by mass in 10 h. The non-isothermal activation energy was  $147 \pm 2$  kJ/mol.

Thermochemical and detonation parameters were calculated for the ionic liquid, 1-ethyl-3-methyl-*H*-imidazolium perchlorate, [emim][ClO<sub>4</sub>] and its associated solid (Table 11) [191]. The effect of azolate anion structure on the physical properties of four ionic liquids, specifically on their glassy dynamics and ion interactions was studied utilizing rheology, X-ray scattering, UV/vis absorption, and *ab initio* calculations [192]. The study used four ionic liquids, three of which shared the same 1-butyl-3-methylimidazolium cation. The anions were tetrafluoroborate, 1-butyl-3-methylimidazolium 4-nitroimidazolate, and 1-butyl-3-methylimidazolium 5-aminotetrazolate. The peculiar rheological behavior for these ionic liquids, which

deviates from the one expected for molecular glass-formers, included high elasticity in the low-frequency zone and failure of time-temperature superposition. These peculiarities were attributed to specific interactions in the nitrogen-rich planar rings of azolate ionic liquids. X-ray scattering measurements revealed a nanometer-ordered organization in azolium azolates due to hydrogen bond interactions. This conclusion was also supported by *ab initio* calculations.

MDs simulation calculations of ionic liquids containing 1-butyl-3-methylimidazolium [bmim] cation and nitrate, azide, or dicyanamidate anions were conducted. A comparison of thermodynamic properties such as densities, enthalpies of vaporization, and ion binding energies, as well as structural correlations obtained from simulations at atmospheric pressure and over the temperature range 298–393 K demonstrated that ionic liquids with the  $\text{N}(\text{CN})_2$  anion showed significantly different characteristics compared to ionic liquids with the  $\text{N}_3$  and  $\text{NO}_3$  anions [193]. This trend was further manifested in dynamical properties characterized by self-diffusion coefficients and molecular rotational relaxation times. For [bmim][ $\text{NO}_3$ ], the simulations gave a value for  $\Delta H_{\text{vap}}$  of 145.8 kJ/mol, which was in good agreement with prior experiments (162.4 kJ/mol). The experimental value of  $\Delta H_{\text{vap}}$  for [bmim][ $\text{N}_3$ ] was very similar to the value of 152.5 kJ/mol predicted from simulations at 298 K. The predicted  $\Delta H_{\text{vap}}$  for [bmim][ $\text{N}(\text{CN})_2$ ] was 195.3 kJ/mol.

Density, viscosity, and surface tension data sets of 13 ionic liquids formed by imidazolium, pyridinium, or pyrrolidinium cations paired with dicyanamidate (dca), tetrafluoroborate, thiocyanate, methylsulfate, and trifluoroacetate anions were measured at temperatures between 293 and 363 K [194]. The effect of the ionic-liquid-forming anion and cation on the physical properties was analyzed systematically. A longer alkyl chain in imidazolium-based ionic liquids was associated with lower density, higher viscosity, and lower surface tension. Density of 1-butyl-3-methylimidazolium dicyanamidate [C4mim][dca]  $\text{C}_{10}\text{H}_{15}\text{N}_5$  at 293.15 K and 100 kPa was  $1.064.4 \pm 0.008 \text{ g/cm}^3$  and viscosity was  $0.0332 \pm 0.0009 \text{ Pa}\cdot\text{s}$ . Additional data can be found in [195–197].

Eight 5-aminotetrazolate (5-AT) salts based on the 1,2,3-trimethylimidazolium (**1**), 1,3-dimethylimidazolium (**2**), 1-ethyl-3-methylimidazolium (**3**), 1-butyl-3-methylimidazolium (**4**), 1-isobutyl-3-methylimidazolium (**5**), 1-(3'-methylbutyl)-3-methylimidazolium (**6**), 1-hexyl-3-methylimidazolium (**7**), and 1-methyl-3-octylimidazolium (**8**) cations have been synthesized and characterized by IR and NMR spectroscopy and elemental analysis [198]. DSC/TGA measured the thermal stabilities of the 5-AT salts. These salts decomposed within the temperature range 296–535 K (230–262°C). Salts **3–8** were very fluent room-temperature ionic liquids, whose glass transition temperatures were quite low. Their viscosities at 303 K (30°C) were in the range from 92 to 208 cPs. Salt (**2**) with the 1,3-dimethylimidazolium cation had the highest positive enthalpy of formation. These 5-AT salts were insensitive to impact (>40 J) and friction (>360 N). Hypergolic reactions of these 5-AT salts with 100%  $\text{HNO}_3$  were also examined but only few ignited.

The imidazole ring already has a good amount of internal energy that is available for forming energetic salts. The energy of imidazolium salts was further increased by first combining two methylimidazole rings with an acetylene molecule to form a di-(methylimidazolyl)acetylene and then replacing the chloride counter ions with either dodecaboranate  $[(B_{12}H_{12})^{2-}]$  or perchlorate anions to gain even more energetic salts [199]. These compounds were characterized by NMR, MS, TGA, and elemental analyses. The enthalpy of formation and heat of explosion of all the compounds were experimentally determined via the enthalpy of combustion. Based on the properties of these compounds, they could be used as insensitive energetic materials in rocket propellants and burn rate accelerators.

*N,N*-Bis(1*H*-tetrazol-5-yl)amine anions (HBTA<sup>-</sup> and BTA<sup>2-</sup>) were used as nitrogen-rich components for the construction of EILs. Seven ionic liquids, namely, 1,3-dimethylimidazolium (1), [C1mim]HBTA, 1-ethyl-3-methylimidazolium (2), [C2mim]HBTA, 1-butyl-3-methylimidazolium (3), [C4mim]HBTA, 1-hexyl-3-methylimidazolium (4), [C6mim]HBTA, 1-methyl-3-octylimidazolium (5), [C8mim]HBTA, and 1,2,3-trimethylimidazolium (6), [C1mmim]HBTA cations with the HBTA<sup>-</sup> anion, and di-1,2,3-trimethylimidazolium *N,N*-bis(1*H*-tetrazol-5-yl)amine (7), [C1mmim]2BTA were synthesized and characterized by IR and NMR spectroscopy, elemental analysis, and high-resolution mass spectrometry [200]. The crystal structures of (1) and (7) were determined by single-crystal XRD (1): monoclinic,  $P2_1/n$ ,  $a = 14.0653(4) \text{ \AA}$ ,  $b = 6.9507(2) \text{ \AA}$ ,  $c = 22.4699(7) \text{ \AA}$ ,  $\beta = 93.996(3)^\circ$ ,  $V = 2191.38(12) \text{ \AA}^3$ ,  $Z = 8$ ,  $\rho = 1.511 \text{ g/cm}^3$ ; (7) monoclinic,  $P2_1/c$ ,  $a = 17.5869(3) \text{ \AA}$ ,  $b = 12.8757(2) \text{ \AA}$ ,  $c = 21.9203(6) \text{ \AA}$ ,  $\beta = 125.0580(10)^\circ$ ,  $V = 4063.15(15) \text{ \AA}^3$ ,  $Z = 8$ ,  $\rho = 1.221 \text{ g/cm}^3$ . The ionic liquids 1–7 were thermally stable up to 493 K (220 °C) and 2–5 were room-temperature ionic liquids. The HOFs of 1–7 obtained by both experimental and theoretical methods were all positive. The ionic liquids 1–7 were insensitive towards impact (>40 J) and friction (>360 N). They could be ignited in air. These new EILs contain only C, H, and N and are of interest as potential propellants with high energy, high thermal stability, low sensitivity to impact and friction, and environmentally friendly decomposition products.

### 7.6.5.2 Multi-Substituted Imidazolium and Imidazolate Salts

1,3-Dimethyl-4-nitroimidazolium nitrate can be prepared by adding silver nitrate to a magnetically stirred solution of 1,3-dimethyl-4-nitroimidazolium iodide in water. After 2 h at room temperature, silver iodide was removed by filtration. The filtrate was dried in vacuo at 333 K (60 °C) to produce colorless needles in 98% yield, m.p. 435–436 K (162–163 °C) [201].

The HOFs were determined for seven of the multi-substituted imidazolium salts [202]. Interestingly, while the 5-nitro perchlorate and nitrate salts had a quite high negative  $\Delta H_f$ 's, the 2-azido salts had modestly high positive  $\Delta H_f$ 's but rather high  $T_m$  values. For example, 2-azidoimidazolium perchlorate had a melting point of 389 K (116 °C), started to decompose at 405 K (132 °C), and had a density of  $1.73 \text{ g/cm}^3$ .

2-azidoimidazolium nitrate had a melting point of 397 K (124 °C), started to decompose at 397 K (124 °C), and had a density of 1.89 g/cm<sup>3</sup>. 1,2,3-trimethyl-5-nitroimidazolium perchlorate had a melting point of 459 K (186 °C), started to decompose at 580 K (307 °C), and had a density of 1.65 g/cm<sup>3</sup>. 1,2,3-trimethyl-5-nitroimidazolium nitrate had a melting point of 434 K (161 °C), started to decompose at 439 K (166 °C), and had a density of 1.52 g/cm<sup>3</sup>.

Ammonium 2,4,5-trinitroimidazolate can be readily prepared by treating an ether solution of 2,4,5-trinitroimidazole with anhydrous ammonia [203]. It is thermally more stable than RDX, melts at 521 K (248 °C), is stable up to 521 K (248 °C), has a density of 1.835 g/cm<sup>3</sup>, an enthalpy of formation of −86.02 kJ/mol, a detonation velocity of 8560 m/s, and a drop weight sensitivity of 50.3 cm with an Explosives Research Laboratory of the National Defense Research Committee (ERL) Type 12 tool [204].

Energetic salts comprising of an energetic 1,2-dimethyl-3-(2-nitrooxyethyl)-imidazolium cation and energetic anions such as nitrate, 3,5-dinitro-1,2,4-triazolate, picrate, 3-nitro-5-oxo-1,2,4-triazolate, dinitromethanide, dinitramide, and 5-nitrotriazolate were easily synthesized via quaternization, nitration, and metathesis and characterized by FTIR, UV-Vis spectroscopy, electrospray ionization mass spectrometry (ESI-MS), NMR, TGA, DSC, and elemental analysis [205]. The salts are typical ionic liquids with glass transition temperatures of 215 to 251 K (−58 to −22 °C) and a melting point below 373 K (100 °C).

## 7.7 Other Imidazole Derivatives

Different amino- and methyl-trinitrodiazoles have been considered as potential candidates for high explosives and their predicted properties were calculated by quantum chemical methods [206]. Geometric and electronic structures, band gap, thermodynamic properties, crystal density, and detonation properties were studied using DFT methods. Presumably, the relative positions of methyl or amino group and nitro groups in the trinitrodiazole would determine the stability, sensitivity, and crystal density and thus detonation performance as an explosive. The chemical energy of explosion (1.35 to 1.47 kcal/g), density (1.93 g/cm<sup>3</sup>), detonation velocity (9.0 to 9.3 km/s), and detonation pressure (38 to 40 GPa) of aminotrinitrodiazoles are comparable to those of RDX and HMX.

### 7.7.1 Biimidazolate Salts

Several salts of 4,4',5,5'-tetranitro-2,2'-biimidazolate were synthesized and characterized [207]. Each of the salts was characterized chemically, thermally, morphologically, as well as with external stimuli (impact, friction, thermal, electrostatic discharge [ESD]). The bis-triaminoguanidinium salt of 4,4',5,5'-tetranitro-2,2'-biimidazole dis-

played a fast-burning rate and had the lowest pressure dependence exponent yet measured for any triaminoguanidinium salt.

Nucleophilic addition reactions of the diammonium salt of 4,4',5,5'-tetranitro-1,1'-biimidazole can form 1,1'-dimethyl-4,4',5,5'-tetranitro-2,2'-biimidazole, 1,1'-diamino-4,4',5,5'-tetranitro-2,2'-biimidazole, or ammonium 1-amino-4,4',5,5'-tetranitro-2,2'-biimidazolate [208].

The diammonium and dihydrazinium salts of 4,4',5,5'-tetranitro-2,2'-biimidazolate (TNBI) were synthesized and characterized [209]. These dianionic salts were easily formed in good yields by the reaction of TNBI with aqueous solutions of the cationic species. TNBI can be synthesized from 2,2'-biimidazole, which can be synthesized via the condensation of aqueous glyoxal with ammonium acetate. The compounds were characterized by density, NMR, FTIR, Raman spectroscopy, elemental analysis, thermal analysis (DSC, vacuum thermal stability [VTS], and calorimetry), and small-scale safety testing (impact, friction, ESD).

*N,N*-Dinitramino imidazole was paired with nitrogen-rich bases, resulting in versatile ionic derivatives which were fully characterized by IR, and <sup>1</sup>H and <sup>13</sup>C NMR spectroscopy and elemental analysis [210].

## 7.8 Pyrazole Derivatives

Pyrazole, 1*H*-pyrazole,  $C_3H_4N_2$ , is a five-membered ring with two vicinal nitrogen atoms

Pyrazole

### 7.8.1 Mono-Substituted Pyrazole Derivatives

Substituents can be added to the pyrazole ring in either the 1, 3, or 4-position (the 5-position would be identical to the 3-position). Nitration in the 1-position would create a cyclic nitramine.

To synthesize the salts of 3-nitropyrazole, *N*-nitropyrazole was first synthesized with pyrazole as raw material and  $HNO_3$ - $Ac_2O$ - $HAc$  as a nitration agent [211]. *N*-nitropyrazole at high temperature was rearranged as 3-nitropyrazole. The structures of products were characterized by melting point, IR, NMR, and elemental analysis. The optimum reaction yield was 85.5% for nitration, 92.8% for rearrangement reaction, and 79.3% for total yield. The copper and lead salts were synthesized by the reaction of 3-nitropyrazole with some inorganic copper and lead salts. The structures of the products were characterized by melting point, IR, NMR, and elemental analysis

The molecular and crystal structure of 3-nitropyrazole was determined by XRD [212]. The triclinic unit cell contains 12 molecules, which form four hydrogen-bonded ( $N-H\cdots N$ ) trimers. Each trimer comprises of a pseudo-ring in a flattened envelope that was distorted towards a chair conformation. *Ab initio* calculations were performed on 3(5)-nitro- and 4-nitropyrazole, and their corresponding protonated forms, to explain the cause for the difference in basicities between the two nitropyrazoles.

*N*-Nitropyrazole is a nitramine; it crystallizes in space group  $P2_1/e$ , monoclinic, with cell parameters of  $a = 7.337(1) \text{ \AA}$ ,  $b = 10.032(1) \text{ \AA}$ ,  $c = 7.199(1) \text{ \AA}$ ,  $\beta = 116.6(2)^\circ$ ,  $M_r = 113.1$ ,  $Z = 4$ ,  $D_{XRD} = 1.585 \text{ g/cm}^3$ . The molecule is planar and the  $\angle O-N-O$  angle,  $128.5(2)^\circ$ , is slightly larger than in other  $N-NO_2$  fragments [213].  $^{14}N$  nuclear quadrupole resonance data for several pyrazoles and 1,2,4-triazoles are listed in [213]. *N*-Nitropyrazole can be prepared by treating pyrazole nitrate with acetic anhydride. The compound is stable and melts at 366 K ( $93^\circ C$ ) without decomposition.

A time-resolved pulsed photoacoustic spectroscopy technique powered by a Nd:YAG laser at the second harmonic, i.e.,  $\lambda = 532 \text{ nm}$ , 7 ns pulse width at 10 Hz repetition rate was used to study the thermal decomposition of 3(5)-nitropyrazole, 4-nitropyrazole, and 1-nitropyrazole [214], examining the effect of pressure, tem-

perature, and incident laser energy on the thermal decomposition mechanism of nitropyrazoles.

### 7.8.2 Di-Substituted Pyrazole Derivatives

Theoretically, six different structural isomers of di-substituted pyrazoles are possible: 1,3-, 1,4-, 1,5-, 3,4-, 3,5-, and 4,5-disubstituted pyrazoles. 3,4-Dinitropyrazole and 4,5-dinitropyrazoles are tautomers, and in solution, they exist as equilibrium mixtures.

A very comprehensive overview of dinitropyrazoles has been compiled, including methods of synthesis and many derivatives that carry other substituents in addition to or in place of nitro groups and chemical reactivities. This is supported by 163 references in the existing literature but these lack a good summary of simple physical properties like melting points and densities [215]. The energies of pyrazoles substituted in the 3- or 5-position are very similar. Pyrazoles that carry nitro groups in the 1- and/or the 3-positions are nitramines. They are more energetic than their C—NO<sub>2</sub> counterparts. Thermal rearrangement of nitro groups in dinitropyrazoles is common. Starting with 1,3-dinitropyrazole or 1,4-dinitropyrazole by simple heating in a solvent like nitrobenzene, one usually ends up with 3,5-dinitropyrazole which is the thermally most stable. Treatment of 1,3-dinitropyrazole with secondary amines results in denitration of the more reactive —NO<sub>2</sub> group from the 1-position. Treatment of 1,4-dinitropyrazole with primary amines results in ring opening. 1,3-Dinitropyrazoles are low-melting (<373 K = <100 °C) oily substances. 2,3-Dinitropyrazoles are better crystallized and melt at higher temperatures (403–473 K = 130–200 °C). 3,4-Dinitropyrazole ( $pK_a = 5.48$ ) and 3,5-dinitropyrazole ( $pK_a = 3.14$ ) are weak acids.

The heats of combustion of 1,2,4-triazole, tetrazole, benzofurazan, 2-nitropyrrole, 4-nitroimidazole, 4-nitropyrazole, 3-nitro-1,2,4-triazole, nitrotetrazole, 3-methyl-4-nitrofuroxan, 5-nitrobenzofurazan, and 5-nitrobenzofuroxan were measured by precision bomb calorimetry. The standard enthalpies of formation were calculated for azoles, oxadiazoles, and the mononitro derivatives [216]. The energetic effect of the introduction of the nitro group into azole heterocyclic compounds on the enthalpy of formation increased in the order pyrrole < imidazole < pyrazole < triazole < tetrazole. The effect was defined as the enthalpy of formation of the nitro derivative minus the enthalpy of formation of the unsubstituted parent amine.

The specific enthalpy of formation of a pyrazole (1702 kJ/kg = 406.9 kcal/kg) is a little higher than that of 1,2,4-triazole (1593 kJ/kg = 380.7 kcal/kg). In the group of azoles, the pyrazole occupies an intermediate position between the high-enthalpy tetrazole (3372 kJ/kg = 806.0 kcal/kg) and low-enthalpy imidazole (859 kJ/kg = 205.2 kcal/kg). The energies of combustion were measured in a calorimeter and the standard enthalpies of formation for a group of derivatives of nitropyrazole were calculated [217] (Table 12). The influence of the number and location of substitution of amino and nitro groups attached to the pyrazole ring on the thermochemical and physicochemical properties of the compounds was analyzed.

**Table 12:** Effect of nitro, amino, and nitramino substituents on the enthalpy of formation of pyrazole compounds.

| Compound                        | Enthalpy of formation |          | Density           |
|---------------------------------|-----------------------|----------|-------------------|
|                                 | kJ/mol                | kcal/mol | g/cm <sup>3</sup> |
| 3-Nitropyrazole                 | +71.5                 | +17.1    | —                 |
| 4-Nitropyrazole                 | +67.8                 | +16.2    | —                 |
| 3,4-Dinitropyrazole             | +120.1                | +28.7    | 1.81              |
| 3,5-Dinitropyrazole             | +93.7                 | +22.4    | 1.8               |
| 1-Methyl-3,4-dinitropyrazole    | +105.4                | +25.2    | —                 |
| 4-Amino-5-nitropyrazole         | +15.1                 | +3.6     | 1.67              |

| 1,4-Dinitropyrazole             | +176.6                | +42.2    | —                 |

Data source: [217].

Using the experimental values of enthalpies of formation and the calculated densities, the heat of explosion and the detonation velocity of the investigated derivative nitropyrazoles were calculated.

3,4-Dinitropyrazole, 3,4-DNP,  $C_3H_2N_4O_4$ ,  $M = 158.07$  g/mol, CAS RN [38858-92-3], has a density of  $1.81$  g/cm<sup>3</sup> and melts at  $359$  K ( $86^\circ\text{C}$ ). 3,4-Dinitropyrazole was synthesized and characterized by IR, elemental analysis, mass spectrometry, and NMR spectroscopy [218]. Its thermal decomposition and phase change were also analyzed with DSC. Its melting point was  $358$ – $360$  K ( $85$ – $87^\circ\text{C}$ ).

A candidate for TNT replacement, 3,4-dinitropyrazole was synthesized from pyrazole via a three-step reaction sequence of nitration, rearrangement, and nitration [219]. The reaction conditions of the third step were optimized to achieve a yield of 41%. The structure was confirmed by  $^1\text{H}$  NMR and IR (see also [220]).

4-Amino-3,5-dinitro-1*H*-pyrazole (LLM-116) was synthesized by a vicarious nucleophilic substitution reaction. Its structure was characterized by NMR, IR, and elemental analysis [221]. The thermal decomposition kinetics and mechanisms were studied using DSC, thermolysis *in-situ* rapid-scan FTIR, and simultaneous TGA-MS analysis. The apparent activation energy and pre-exponential factor of the exothermic decomposition reaction of LLM-116, obtained by the Kissinger method, were  $107$  kJ/mol,  $10^{10}$  s<sup>−1</sup> in the first decomposition stage, and  $139$  kJ/mol,  $10^{12}$  s<sup>−1</sup> in the second decomposition stage. The decomposition of LLM-116 begins with one molecular water lost by  $-\text{NO}_2$  and  $-\text{NH}_2$ , forming a furazan in the LLM-116 structure.

The decomposition of 3,4-dinitropyrazole (DNP) and two model molecules (4-nitropyrazole and 1-nitropyrazole) was investigated both theoretically and experimentally [222]. The initial decomposition mechanisms for these three nitropyrazoles were explored with computational methods. The NO molecule was observed as an initial

decomposition product from all three materials after UV excitation. The theoretically predicted mechanism was consistent with experimental results; DNP decomposed in a lower electronic state than the model systems did. Thus the vibrational energy in the NO product from DNP should be hotter than from the model systems. The observed rotational energy distributions for NO were consistent with the final structures of the respective transition states for each molecule.

The thermal decomposition under non-isothermal and isothermal conditions, burning behavior, and flame structure of dinitropyrazoles, such as 3,4-dinitro-1*H*-pyrazole (3,4-DNP), *N*-(3,5-dinitro-1*H*-pyrazol-4-yl)-[1,2,4]triazolo[3,4-*b*][1,2,4,5]tetrazin-6-amine (ADNPTrTz), and 3,3',4,4'-tetranitro-1,1'*H*-bipyrazole-5,5' (TNBP) in the liquid phase lies between the stability of nitramines RDX and HMX [223]. The decomposition of dinitropyrazole moiety in 3,4-DNP and TNBP starts from a nitro group loss. If the nitropyrazole molecule contains an amino group, the thermal decomposition may begin with an NO<sub>2</sub> group isomerization, followed by decomposition of either the pyrazole ring or formed furazan ring. The pyrazole moiety is resistant to oxidation by NO<sub>2</sub>, leading to a low heat effect at the initial decomposition stages. This results in difficulties with determining real kinetics from DSC experiments. The activation energy of decomposition of 4-amino-3,5-dinitro-1*H*-pyrazole appeared to be rather low (108.8 kJ/mol). This might be indicative of a possible hazard in handling this compound even though its onset of decomposition temperature was high enough. 4-Amino-3,5-dinitropyrazole (ADNP) and 3,4-dinitro-1*H*-pyrazole (3,4-DNP), *N*-(3,5-dinitro-1*H*-pyrazol-4-yl)-[1,2,4]triazolo[3,4-*b*][1,2,4,5]tetrazin-6-amine burned only with combustion instability at low pressures and TNBP did not burn at pressures below 15 MPa.

A comparative study of the thermal stability and combustion parameters of three dinitropyrazole isomers showed that the rate-limiting stage of the decomposition of 1,3-dinitropyrazole (1,3-DNP) and 1,4-dinitropyrazole (1,4-DNP) – both having the *N*-bounded nitro group – is the N C migration of the nitro group rather than its elimination, followed by secondary decomposition reactions of the non-aromatic 3*H*-pyrazole [224]. In the case of 3,4-dinitropyrazole (3,4-DNP), the rate-limiting stage was assumed to be the nitro group elimination. The burning rate versus pressure dependences of all the studied pyrazole isomers were similar to each other, despite significant differences in the thermal stability and volatility.

A study of the thermal decomposition, burning behavior, and flame structure of low-melting oxygen-rich energetic *N*-trinitromethyl-3,4-dinitropyrazole (**1**), *N*-trinitromethyl-3,5-dinitropyrazole (**2**), *N*-fluorodinitromethyl-3,5-dinitropyrazole (**3**), and *N*-[(difluoroamino)dinitromethyl]-3,5-dinitropyrazole (**4**) showed that the stability of *N*-trinitromethyl azoles is higher than the stability of similar *C*-trinitromethyl heterocycles [225]. Replacing one nitro group in the trinitromethyl moiety with fluorine or difluoroamine group changed the C–NO<sub>2</sub> bond length and the thermal stability. However, there was no linear correlation between the rate constants and the C–NO<sub>2</sub> bond length. This indicated the presence of other factors affecting

the stability of trinitro- and substituted dinitromethylpyrazole derivatives. The burning rates of the nitropyrazoles varied from 26.8 mm/s (for **1**) to 77.5 mm/s (for **4**) at 10 MPa. The increased thermal stability of the fluorodinitromethyl compound (**3**) caused a decrease in its decomposition in the melt and shifted the main reaction of its combustion into the gas phase. A two-stage decomposition mechanism was indicated by different thermal stabilities of the substituent and the dinitropyrazole fragment.

The synthesis and characterization of 1*H*,4*H*-3,6-dinitropyrazolo[3,4-*c*]pyrazole amine salts opened a new path to energetic salts [226]. 3-Cyano-4-nitropyrazole, 4-nitro-1*H*-pyrazole-3-carbonitrile; 1*H*-pyrazole-3-carbonitrile, 4-nitro-;  $C_4H_2N_4O_2$ ,  $M = 138.09$  g/mol, CAS RN [61241-07-4] (also recognized under the code name of LLM-162) has been evaluated as a burning rate modifier. It melts at 426 K (153 °C) and has a density of 1.659 g/cm<sup>3</sup>.

3-Cyano-4-nitropyrazole

### 7.8.3 Tri-Substituted Pyrazole Derivatives

4-Amino-3,5-dinitropyrazole, also known as 3,5-dinitro-1*H*-pyrazol-4-amine,  $C_3H_3N_5O_4$ , ADNP, HANP,  $M = 173.09$  g/mol, CAS RN [152678-73-4], LLM-116, was synthesized in 70% yield from 3,5-dinitropyrazole via treatment with 1,1,1-trimethylhydrazinium iodide in dimethylsulfoxide (DMSO) in the presence of two equivalents of potassium 1-butoxide [227, 228].

4-Amino-3,5-dinitropyrazole (LLM-116)

LLM-116 has a density of 1.90 g/cm<sup>3</sup>, an onset of decomposition point of 451 K (178 °C), and has an impact sensitivity of 50% at a drop height of 165 cm with a 2.5-kg drop mass. LLM-116 is predicted to have 90% of the power of HMX.

High-density energetic salts from nitrogen-rich cations and the 3,4,5-trinitropyrazolate anion were synthesized by neutralization or metathesis reactions and characterized by  $^1\text{H}$ ,  $^{13}\text{C}$  NMR, IR, DSC, and elemental analysis [229, 230]. The structures of the 3,5-diaminotriazolium and triaminoguanidinium 3,4,5-trinitropyrazolates were determined by single-crystal XRD. Based on the measured densities and calculated HOFs, the detonation performances of the 3,4,5-trinitropyrazolate salts were comparable with 1,3,5-triamino-2,4,6-trinitrobenzene (TATB). Impact sensitivities were determined to be no less than 35 J by drop weight impact tests, which places these salts in the insensitive class.

3,4,5-Trinitropyrazole can be made by nitrating 3,5-dinitropyrazole with nitric acid in oleum [231]. It is a strong acid and forms energetic salts with a variety of bases. The nitro group in the 4-position of 3,4,5-trinitro-1*H*-pyrazole is easily replaced by nucleophilic reagents [232]. The crystal structure of 3,4,5-trinitro-1*H*-pyrazole was initially assigned to space group  $C2/c$  but a critical investigation revealed that it should be  $P2_1/c$  [233]. The crystal unit cell parameters are  $a = 15.0080(5) \text{ \AA}$ ,  $b = 8.1732(3) \text{ \AA}$ ,  $c = 17.1160(5) \text{ \AA}$ ,  $\alpha = 90^\circ$ ,  $\beta = 92.2510(10)^\circ$ ,  $\gamma = 90^\circ$ ,  $Z = 3$ .

The thermal decomposition of 3,4,5-1*H*-trinitropyrazole (TNP), 1-methyl-3,4,5-1*H*-trinitropyrazole (MTNP), and ammonium 3,4,5-1*H*-TNP has been studied experimentally by TGA and DSC at four different heating rates (1, 2, 5, and 10 K/min) [234]. At a heating rate of 2 K/min, the onset of exotherm of TNP was 456 K (183 °C) and the maximum peak temperature was 487 K (214.2 °C). At a heating rate of 5 K/min, the onset was at 457.7 K (184.6 °C) and the max was at 501.4 K (228.3 °C). The ammonium salt of TNP was thermally more stable than its parent acid. At a heating rate of 2 K/min, the onset of exotherm was at 469 K (195.9 °C) and the peak max was at 471.7 K (198.6 °C). At a heating rate of 5 K/min, the onset was at 479 K (205.9 °C) and the peak max was at 481.6 K (208.5 °C). The activation energy of TNP decomposition was  $E_a = 127.3 \text{ kJ/mol}$  and the activation energy of the decomposition of its ammonium salt was 231.9 kJ/mol, again showing that the ammonium salt is more stable than its parent acid. Ammonium 3,4,5-trinitropyrazolate,  $\text{C}_3\text{H}_4\text{N}_6\text{O}_6$ ,  $[\text{NH}_4^+][\text{C}_3\text{N}_5\text{O}_6^-]$ ,  $M = 220.1 \text{ g/mol}$  (which is also referred to as its code name of LLM-165) has a density of  $1.729 \text{ g/cm}^3$  and decomposes at 469–472 K (196–199 °C) without prior melting.

3,4,5-Trinitropyrazole-1-ol and its nitrogen-rich ammonium and triazolium salts were synthesized and well-characterized by  $^1\text{H}$ ,  $^{13}\text{C}$  NMR, IR spectroscopy, elemental analysis, and XRD [230, 235]. 3,4,5-trinitropyrazole-1-ol and its salts have densities from  $1.72$  to  $1.90 \text{ g/cm}^3$ , the onset of thermal decomposition  $T_{\text{dec}}$  from 391 to 459 K = 118 to 186 °C, detonation pressures of 28.77 to 36.40 GPa, detonation velocities of 8175 to 8676 m/s, and impact sensitivities of 1 to 40 J.

4-Amino-3,5-dinitropyrazole (HANP) can be prepared by nitration of pyrazole with fuming nitric acid, followed by the thermal rearrangement of *N*-nitropyrazole in benzonitrile and amination with 1,1,1-trimethylhydrazinium iodide. Reactions of the acidic HANP with bases such as ammonia, hydrazine, guanidinium carbonate, aminoguanidinium bicarbonate, triazole, 3-aminotriazole, 4-aminotriazole, 3,5-di-

**Table 13:** Properties of 4-amino-3,5-dinitropyrazolate salts.

Data source: [229,236].

aminotriazole, and carbohydrazide resulted in the formation of salts. 4-amino-3,5-dinitropyrazole with a crystal density of 1.90 g/cm<sup>3</sup> has a structure similar to TATB and is easily deprotonated to form a 4-amino-3,5-dinitropyrazolate anion. Fifteen nitrogen-rich 4-amino-3,5-dinitropyrazolate energetic salts were prepared and characterized by <sup>1</sup>H, <sup>13</sup>C, and <sup>15</sup>N NMR, IR spectroscopy, DSC, elemental analysis, and drop weight impact tests [236]. The properties of a select group of six of the 15 salts are shown in Table 13 as examples.

Some salts decomposed without melting while others melted with decomposition. The HOF was measured or calculated. With one exception, all HOFs were positive with the highest value at +1.64 kJ/g. As highly insensitive energetic materials, the performance of some of the salts was comparable with that of 1,3,5-triamino-2,4,6-trinitrobenzene (TATB, 31.15 GPa and 8114 m/s).

#### 7.8.4 Tetra-Substituted Pyrazole Derivatives

There are only four positions on the pyrazole ring that can be substituted with ligands other than hydrogen. Ideally, if all four hydrogens could be replaced with nitro groups, the result would be an explosive with a positive oxygen balance (+12.9%).

The molecular structures of 3,4,5-trinitro-1*H*-pyrazole, 3,4,5-trinitro-1*H*-pyrazol-1-amine, 1-methyl-3,4,5-trinitro-1*H*-pyrazole, and 1,3,4,5-tetranitro-1*H*-pyrazole have been calculated by quantum chemical MO methods [237]. The geometric and electronic structures, band gap, thermodynamic properties, crystal density, and detonation properties were studied using DFT methods. The calculated energy of explosion, density, and detonation performance of model compounds are comparable to RDX and HMX. It is important to understand the nature of intra-molecular interactions and the strength of trigger bonds.

*Ab initio* MO calculations have been carried out to explore the structure, stability, sensitivity, and band gap of nitropyrazoles [238]. Kamlet and Jacobs equations were used to calculate the detonation velocity and detonation pressure of the paper-designed compounds. The explosive properties of polynitropyrazole-*N*-oxides appeared to be more attractive compared to those of ONC and 2,4,6,8,10,12-hexanitro-2,4,6,8,10,12-hexaazaisowurtzitane. The sensitivity, heat of explosion, density, detonation velocity, and detonation pressure are presumably related to the number and the relative positions of NO<sub>2</sub> groups on the pyrazole ring.

MO calculations were performed for the geometric and electronic structures, band gap, thermodynamic properties, density, detonation velocity, detonation pressure, stability, and sensitivity of 1,3,4,5-tetranitropyrazole (R23) [239]. The calculated density (approx. 2.06 g/cm<sup>3</sup>), detonation velocity (approx. 9242 m/s), and detonation pressure (approx. 41.30 GPa) of the model compound are promising compared to RDX or HMX.

Enthalpies of formation ( $\Delta H_f^\circ$ ) in the gas phase of a group of five substituted imidazole, pyrazole, 1,2,3-triazole-, 1,2,4-triazole-, and tetrazole-based energetic materials were theoretically investigated by employing DFT and isodesmic reaction calculations [156]. The BDEs corresponding to NO<sub>2</sub>, NH<sub>2</sub>, CH<sub>3</sub>, and Cl removal from carbon or nitrogen positions of the azole ring were calculated. The substituent effect of electron-withdrawing (NO<sub>2</sub>, Cl) and electron-donating (NH<sub>2</sub>, CH<sub>3</sub>) groups affects the  $\Delta H_f^\circ$ , BDE, stability, and acidity/basicity of these molecules. Both EWG and electron-donating groups (except the CH<sub>3</sub> group) increased the  $\Delta H_f^\circ$  of these energetic materials when the substituent was at an N position on the azole ring. For substitution at a C atom on the azole ring, electron-withdrawing and electron-donating groups had different effects on the  $\Delta H_f^\circ$  for different azole compounds. A correlation was developed for this series of energetics between impact sensitivity  $h_{50\%}$  and the defined sensitivity index. Based on this empirical relationship and its extrapolation, the impact sensitivities of compounds for which experiments were not available were extrapolated. Five different compounds were identified as the most promising energetic compounds, which have potentially good energetic performance and low sensitivity: 1-amino-2,4,5-trinitroimidazole (**1**), 1-amino-3,4,5-trinitropyrazole (**2**), 1,4-dinitro-1,2,3-triazole (**3**), 1-nitrotetrazole (**4**), and 1,3-dinitro-1,2,4-triazole (**5**).

### 7.8.5 Pyrazolium Salts and Pyrazolate Salts

Pyrazolium nitrate can be prepared by first drying pyrazole under vacuum for 30 min., cooling in an ice bath, and adding trifluoroacetic anhydride (TFAA) through a septum, then very slowly adding 70% nitric acid [201]. After the complete addition of nitric acid, the mixture should then be left to stir at room temperature for 12 h. 4-Nitropyrazole and 4-nitropyrazolium nitrate is a byproduct of this process. The solvent should then be removed under vacuum, following which recrystallization of the crude product from ethyl acetate produces pyrazolium nitrate as white needles in 65% yield, m.p. 420–421 K (147–148 °C). Pyrazolium nitrate crystallizes from ethyl acetate as thin needles in the monoclinic space group  $P2_1/c$ . The onset of exotherm in the DTA is at 393 K (120 °C).

Unfortunately, it was found that 4-nitroamino-3,5-dinitropyrazole itself was unstable at room temperature. 4-Nitramino-3,5-dinitropyrazole was prepared by nitrating 4-amino-3,5-dinitropyrazole with mixed acid and stabilized through the formation of its ammonium salt. With selected cations, 14 nitrogen-rich energetic salts were synthesized by metathetical reactions replacing the ammonium and characterized by  $^1\text{H}$ ,  $^{13}\text{C}$  NMR, IR, and elemental analysis [240]. The resulting energetic salts showed acceptable thermal stability, detonation performance, and impact sensitivity. The structures of the ammonium, 3,4,5-triaminotriazolium, and biguanidinium salts were determined by single-crystal XRD. Based on experimental and calculated values, the 4-nitramino-3,5-dinitropyrazolate salts revealed properties

such as decomposition temperatures, detonation pressures and velocities, and impact sensitivities that place them in line with energetics such as RDX and TATB. The properties of a distinct group of five salts selected from the list of 14 salts are summarized in Table 14.

**Table 14:** Properties of 4-nitramino-3,5-dinitropyrazolate salts.

| Compound No.    | Compound name                                                  | $T_{\text{dec}}$ |     | $\rho$ | $\Delta H_f$ salt |       | $P_{\text{det}}$ | $v_{\text{det}}$ |

### 7.8.6 Azopyrazole Derivatives

A nitrogen-rich polynitro energetic compound with an  $-\text{N}=\text{N}-$  azo linkage, 1,1'-azobis(3,5-dinitropyrazole), (ABDNP), bis(3,5-dinitropyrazol-1-yl)diazene, was synthesized using 3,5-dinitropyrazole (DNP) as starting material via neutralization, *N*-amination, and oxidative coupling reaction. Its structure was characterized by IR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, MS, and elemental analysis [241].

1,1'-Azobis(3,5-dinitropyrazole)

The effects of oxidizing agents on the coupling reaction were investigated. Results showed that *tert*-butyl hypochlorite (*t*-BuOCl) was a better oxidizing agent with a yield of ABDNP up to 43.5%. At a packing density of 1.94 g/cm<sup>3</sup>, the predicted detonation velocity was 9309 m/s. Detonation pressure was 42.2 GPa, which is better than that of RDX.

### 7.8.7 Bipyrazole Derivatives

4,4',5,5'-Tetranitro-2,2'-bis(trinitromethyl)-3,3'-bipyrazole, also known as 5-[4,5-dinitro-2-(trinitromethyl)pyrazol-3-yl]-3,4-dinitro-1-(trinitromethyl)pyrazole, was obtained by *N*-alkylation of 4,4',5,5'-tetranitro-2*H*,2'*H*-3,3'-bipyrazole with bromoacetone and subsequent nitration [242].

X-ray single-crystal diffraction confirmed its structure and revealed a unique high crystal density of 2.021 g/cm<sup>3</sup> at room temperature, introducing it into the group of top three of the densest CHNO compounds known. This high-density material has an attractive positive oxygen balance, acceptable sensitivity, and enthalpy of formation (on a unit of weight) similar to 2,4,6,8,10,12-hexanitro-2,4,6,8,10,12-hexaazaisowurtzitane (CL-20). With calculated specific and effective impulses exceeding those of AP and ADN, it makes it a competitive replacement for AP as a green energetic oxidizer for solid propellants.

## 8 Triazoles

Triazoles are five-membered ring-shaped molecules that contain three nitrogen atoms at either the 1,2,3 or 1,2,4-positions in the ring. In the five-membered ring of triazoles, the three nitrogens can be either in vicinal (adjacent) positions (1,2,3-triazole, CAS RN [288-36-8]) or separated by a carbon atom (1,2,4-triazole, CAS RN [288-88-0]) [243].

Note that sometimes authors omit the “a” in triazole and call these compounds **trizole** instead (in analogy to tetrazole and pentazole).

1,2,3-Triazole

1,2,4-Triazole

Sometimes the structure is made more specific by adding the location of the hydrogen atom, e.g., in *1H*-1,2,3-triazole [244, 245]. The physical properties of triazoles are summarized in Table 15.

Triazoles are amphoteric. There is a substantial amount of interest in salts formed by either triazolium cations or triazolate anions. These salts are formed mostly with substituted triazoles and only occasionally with the unsubstituted parent triazole itself. The properties of the neutral triazole compounds are summarized here and are followed by several chapters on triazolium and triazolate salts. There is some overlap between these three sections. The *pK* of 1,2,4-triazole is 10.04 and that of 1,2,3-triazole is 8.2. Triazoles mostly act as a base when reacted with strong acids [246].

**Table 15:** Physical properties of triazoles.

| Property                                 | 1 <i>H</i> -1,2,3-Triazole | 1 <i>H</i> -1,2,4-Triazole | 4-Amino-1,2,4-triazole, 4 <i>H</i> -1,2,4-triazol-4-amine | 3,4,5-Triamino-1,2,4-triazole; 4 <i>H</i> -1,2,4-triazole-3,4,5-triamine, guanazine |

| Standard enthalpy of formation, kcal/mol | —                          | +26 (measured)             | —                                                         | —                                                                                   |
| Standard enthalpy of formation, kJ/mol   | +272 (calculated)          | +109 (measured)            | +318                                                      | +234 (calculated)                                                                   |

There are now many synthetic methods that lead to triazoles and triazole derivatives [247]. There are many applications for 1,2,4-triazoles other than as rocket propellants. 1,2,4-Triazole and 1,2,4-triazole derivatives can be prepared by **(1)** cyclizations to form a triazole ring, **(2)** transformations of heterocyclic compounds to construct a triazole ring, **(3)** substitutions on a 1,2,4-triazole ring, and **(4)** structural modifications in side chains of 1,2,4-triazole rings [248].

## 8.1 Physical and Chemical Properties of Triazole and Triazole Derivatives

The physical properties of triazoles and two triazole derivatives are summarized in Table 15. Both triazoles are commercially available.

Other sources give the enthalpies of formation of 1,2,4-triazole and 1,2,3-triazole as +109 and +272 kJ/mol, respectively. The heats of combustion of a wide range of triazole and tetrazole derivatives have been determined and the enthalpies of formation can be derived from these numbers [249, 250]. The following sections detail the properties of neutral molecule (not a salt) triazoles. Sections on triazolium and triazolate salts are further down in this chapter.

## 8.2 Mono-Substituted 1,2,3-Triazole Derivatives

1-Amino-1,2,3-triazole is identical with 3-amino-1,2,3-triazole. 1,2,3-Triazoles with a phenyl ring attached in the 1-position were synthesized by cycloaddition reactions between phenyl azides and alkynes, followed by nitration [251]. The phenyl ring could carry a nitro group or a methoxy group in the 2-, 3-, or 4-position to start with. Additional nitro groups could be introduced once the aryltriazole has been formed. The additional nitration may also place a nitro group on the triazole ring in the 4-position. Most of the polynitro-bearing triazole derivatives decomposed within the range 415–592 K (142–319 °C). Their HOFs and crystal densities and detonation velocities and pressures were calculated. Most of these compounds exhibited high positive HOFs, good thermal stabilities, reasonable densities, and acceptable detonation properties that were comparable to those of TNT. Similar compounds, for instance, a pyridine with two triazole rings attached, were obtained by reacting pyridyl (di)azide with alkynes.

The explosive power of 1,2,3-triazole increases if one or more nitro groups are introduced into the molecule, such as in 4-nitro-2*H*-1,2,3-triazole or 4,5-dinitro-2*H*-1,2,3-triazole [252]. The reaction of 3-amino-1-nitroguanidine with tri-Et orthoformate leads to the formation of 3-nitramino triazole [253].

### 8.3 Di-Substituted 1,2,3-Triazole Derivatives

One example for an energetic di-substituted 1,2,3-triazole derivative is 4-azido-5-nitro-2*H*-1,2,3-triazole,  $C_2H_1N_7O_2$ ,  $M = 155.08$  g/mol. It has a density of  $1.777$  g/cm<sup>3</sup> and is also known by the code name LLM-134. The condensation of ethyl 2,2-dinitroacetate with acetaldehyde in the presence of  $NaN_3$  gave 4-methyl-5-nitro-1,2,3-triazole, which was converted to 4-amino-5-nitro-1,2,3-triazole [254]. Their structures were confirmed by IR, NMR, DSC, and elemental analysis. 4-Amino-5-nitro-1,2,3-triazole; 1*H*-1,2,3-triazol-4-amine, 5-nitro-;  $C_2H_3N_5O_2$ , ANTZ, CAS RN [145769-58-0],  $M = 129.08$  g/mol, melts at  $570$  K ( $297^\circ\text{C}$ ) and has a density of  $1.835$  g/cm<sup>3</sup>. 4,5-Dinitro-1,2,3-triazole forms an ammonium salt that is relatively stable and would make a good propellant ingredient. Ammonium 4,5-dinitro-1,2,3-triazolate; 4,5-dinitro-1,2,3-triazole, ammonium salt; ADNTr,  $C_2H_4N_6O_4$ ,  $M = 176.09$  g/mol, melts at  $441$  K ( $168^\circ\text{C}$ ) (decomposition) and has a density of  $1.716$  g/cm<sup>3</sup>.

### 8.4 Other Di-Substituted 1,2,3-Triazole Derivatives

Attaching two tetrazole rings to 1,2,3-triazole in the 4- and 5-positions creates a compound with an extremely high nitrogen content that would be a good ingredient for gas generator formulations. 4,5-Di(tetrazol-5-yl)-1,2,3-triazole; 2*H*-tetrazole, 5-[4-(2*H*-tetrazol-5-yl)-1*H*-1,2,3-triazol-5-yl]-;  $C_4H_3N_{11}$ , LLM-137, CAS RN [869060-66-2],  $M = 205.14$  g/mol, has a predicted density of  $\rho = 2.035$  g/cm<sup>3</sup>. This compound is made by reaction of 4,5-dicyano-1,2,3-triazole with hydrogen azide [255, 256]. This compound is slightly acidic (predicted  $pK_a = -0.15 \pm 0.10$ ) and can form salts with a variety of bases.

### 8.5 Tri-Substituted 1,2,3-Triazole Derivatives

Energetic derivatives of 5-nitro-1,2,3-2*H*-triazole, which include 2-(methyl or amino)-4-(nitramino, azido, or nitro)-5-nitro-1,2,3-2*H*-triazoles, were prepared and characterized by NMR, IR, DSC, densities, detonation pressures and velocities, impact sensitivities, and elemental analysis [257]. Among the several new derivatives, 2-amino-4,5-dinitro-1,2,3-2*H*-triazole exhibited favorable properties ( $T_m = 367$  K =  $94^\circ\text{C}$ ;  $T_{dec} = 463$  K =  $190^\circ\text{C}$ ;  $\rho = 1.83$  g/cm<sup>3</sup>;  $P_{det} = 36.2$  GPa,  $v_{det} = 8843$  m/s, impact sensitivity 24 J) that was comparable with RDX.

## 8.6 Azo-1,2,3-Triazole Compounds

The construction of a catenated nitrogen chain of eight nitrogen atoms was achieved through oxidative azo coupling of the  $\text{N}-\text{NH}_2$  moiety, where the amino group attached to a triazole ring was first transformed into a diazonium ion under acidic conditions. A subsequent nucleophilic attack of the amino group of the 1-amino-1,2,3-triazole on this diazonium cation produced an unusual structure containing eight catenated nitrogen atoms: 1,1'-azobis-1,2,3-triazole (1,1'-azo-1,2,3-triazole, bis(triazol-1-yl)diazene) has a nitrogen content of 68.27% [258]. This N8 compound is thermally stable up to 466 K (193 °C) and has a relatively high enthalpy of formation of +962 kJ/mol.

1,1'-Azo-1,2,3-triazole

## 8.7 Physical and Chemical Properties of 1,2,4-triazole

The physical properties of 1,2,4-triazole have already been summarized in Table 15.

1,2,4-Triazole

The thermal decomposition behavior of 1H-1,2,4-triazole at low and high temperatures was studied by product-gas-analysis using flash pyrolysis [259]. In the case of low-temperature decomposition, hydrogen cyanide and ammonia were detected as decomposition product gases, and hydrogen cyanide and methane were detected in high-temperature decomposition products. It was supposed that the decomposition mechanism is different below and above 873–973 K (600–700 °C). One theory is that singlet nitrilimine decomposed to form hydrogen cyanide and NH. Conversely, triplet nitrilimine could have formed methane; the reaction path to form methane would be similar to the decomposition of 1H-tetrazole. However, triazole decomposition generated no acetylene while tetrazole released acetylene and methane. The difference could be explained in terms of the HOF of triazole and tetrazole.

Because 1,2,4-triazole is readily available and can be made in high purity, it has been considered a reference material (similar to benzoic acid) with a known heat of combustion for calibrating the combustion calorimetry of nitrogen-containing organic compounds [260].

## 8.8 Mono-Substituted 1,2,4-Triazole Derivatives

The 1,2,4-triazole ring can carry substituents in various positions, preferably on the carbon atom in positions three and five. But 1,2,4-triazole derivatives where a side group has been attached in the 1-position on the nitrogen atom are also known [261, 262]. Highly energetic compounds can be obtained by attaching 1,2,4-triazole rings (with or without substituents on the triazole ring) to tetrazole rings in the 5-position of the tetrazole ring [263].

### 8.8.1 1-Amino-1,2,4-triazole

*N*-substituted triazoles can be prepared either by direct synthesis during ring closure or by alkylation of 1,2,4-triazole [264]. The isomer 1-amino- $\alpha$ -vic-triazole or 1-amino-1*H*-1,2,3-triazole melts at 324 K (51°C) and explodes soon after this temperature is exceeded. It contains four connected nitrogen atoms. Additional substitution with methyl groups stabilizes the molecule somewhat.

### 8.8.2 3-Amino-1,2,4-triazole

The pendant amino group can be attached to either a carbon or a nitrogen atom in the triazole ring. 3-Amino- $\alpha$ -sym-triazole, 3-amino-1*H*-1,2,4-triazole, 1*H*-1,2,4-triazolyl-3-amine, amitrole, 1,2,4-triazol-3-amine, aminotriazole,  $C_2H_4N_4$ , 3-AT, CAS RN [61-82-5] may also be called 5-amino-1,3,4-triazole. It forms yellow crystals, has a melting point of 432 K (159°C), and sublimes and partially decomposes at higher temperatures. Its density is 1.138 g/cm<sup>3</sup>. It can exist in several tautomeric structures:

Tautomeric forms of 3-amino-1*H*-1,2,4-triazole

3-Amino-1*H*-1,2,4-triazole is commercially available and is widely used as an herbicide and cotton defoliant. 3-AT is a non-selective systemic herbicide used on non-food croplands to control annual grasses, broadleaf, and aquatic weeds. It is not used on food crops because of its carcinogenic properties. As an herbicide, it is known as aminotriazole, amitrole, or amitrol. It is very soluble in water (280 g/L). The IR spectrum of 3-amino-1*H*-1,2,4-triazole is shown in Figure 6.

Its nitrate salt, 3-amino-1*H*-1,2,4-triazolium nitrate,  $C_2H_5N_5O_3$ , has an oxygen balance of -38.1%, a nitrogen content of 47.61%, and melts at 453.6–454.6 K (180.5–181.5°C) with incipient decomposition. The standard enthalpy of formation of

**Figure 6:** IR spectrum of 3-amino-1*H*-1,2,4-triazole. (Reproduced and modified from Sigma-Aldrich.)

3-amino-1*H*-1,2,4-triazole is +76.8 kJ/mol (+18.36 kcal/mol) and the standard enthalpy of formation of its nitrate salt is −589 kJ/mol (−140.89 kcal/mol) [250].

The pendant amino group can be attached to either a carbon or a nitrogen atom in the triazole ring. 1-Amino-1,2,3-triazole is a hydrazine derivative with four catenated nitrogen atoms.

A new preparation method of 1-amino-1,2,3-triazole has been developed [265]. Glyoxal bishydrazone, which was synthesized from glyoxal and aqueous hydrazine, was oxidized with manganese(IV) dioxide to give 1-amino-1,2,3-triazole with the yield of 78.30%. The structure of 1-amino-1,2,3-triazole was confirmed by IR, NMR, MS, and elemental analysis. 1-amino-1,2,3-triazole with high purity (96%) can be obtained by crystallization from acetonitrile.

### 8.8.3 4-Amino-1,2,4-triazole

The pendant amino group can be attached to either a carbon or a nitrogen atom in the triazole ring. The most common aminotriazole is 4-amino-4*H*-1,2,4-triazole, 4-amino-1,2,4-triazole, 1,2,4-triazol-4-amine, ATA, C<sub>2</sub>H<sub>4</sub>N<sub>4</sub>, CAS RN [584-13-4], where the amino group is attached to a nitrogen atom.

4-Amino-1,2,4-triazole

The amino group in 4-amino-1,2,4-triazole is attached to a nitrogen atom in the 4-position. The N—N bond indicates that its synthesis starts with hydrazine. 4-amino-1,2,4-triazole can be readily synthesized from formic acid and hydrazine in the presence of catalysts. Formylhydrazine is an intermediate in this reaction but it does not have to be isolated if the aminotriazole is the desired product. 4-Amino-1,2,4-triazole forms hygroscopic needles that melt at 355–356 K (82–83 °C) and are readily soluble in water or hydrochloric acid. The enthalpy of formation of 4-amino-1,2,4-triazole is +318 kJ/mol. 4-Amino-1,2,4-triazole is available commercially (this is not to be confused with 3-amino-1,2,4-triazole, which is produced in larger quantities).

The enthalpy of formation of 4-amino-1,2,4-triazole, which is commonly referenced in the literature as +318.0 kJ/mol, appears to be too high. More recently a new value was published ( $+222.8 \pm 1.8$  kJ/mol), which is in good agreement with the theoretical prediction. Calorimetric bomb work resulted in an enthalpy of formation of  $+223.5 \pm 2$  kJ/mol [266, 267].

$\mu$ -Tris(4-amino-1,2,4-triazole)copper(II) diperchlorate  $[\text{Cu}(\text{C}_2\text{H}_4\text{N}_4)_3][\text{ClO}_4]_2$  is a primary explosive detonator with performance close to that of lead azide. However, it is also quite a stable compound that shows moderate sensitivity to thermal and mechanical stimuli [268]. The thermal decomposition kinetics was studied and detonation and explosion parameters (detonation heat and velocity, acceleration ability, water shock wave overpressure, and energy) were measured and/or calculated. 4-Amino-1,2,4-triazole as a ligand forms coordination compounds with metal salts [269].

Twelve salts formed by the reaction of the bases 4-amino-1,2,4-triazole (**A**), 1-amino-1,2,4-triazole (**B**), and 5-aminotetrazole (**C**) upon reaction with the acids  $\text{HNO}_3$ ,  $\text{HN}(\text{NO}_2)_2$ ,  $\text{HClO}_4$ , and  $\text{HC}(\text{NO}_2)_3$  were studied using DFT calculations [270]. For the reactions with the same base, those of  $\text{HClO}_4$  were the most exothermic and had the highest decomposition temperature of the resulting salt. The ability of anions and cations to form hydrogen bonds decreased in the order  $\text{NO}_3^- > \text{N}(\text{NO}_2)_2^- > \text{ClO}_4^- > \text{C}(\text{NO}_2)_3^-$  and  $\text{C}^+ > \text{B}^+ > \text{A}^+$ . For the salts with the same anion, the larger total hydrogen-bond energy leads to a higher melting point. For the production of energetic salts, 5-aminotetrazole and  $\text{HClO}_4$  were identified as the preferred base and acid, respectively.

The single-crystal structure of the salt formed by the reaction of 4-amino-1,2,4-triazole with 3-nitro-1,2,4-triazole-5-one (NTO) was determined by XRD [271]. The results showed that the crystal is monoclinic, belonging to space group  $P21/c$  with main crystallography parameters  $a = 7.071(2)$  Å,  $b = 6.361(3)$  Å,  $c = 18.792(7)$  Å,  $\beta = 96.43(3)^\circ$ ,  $V = 839.9(5)$  Å<sup>3</sup>,  $Z = 4$ ,  $\rho_c = 1.694$  g/cm<sup>3</sup>. The standard volume of gas evolved in the vacuum stability test (VST) at 100 °C during 48 h was 0.28 mL/g. The 50% drop height of impact sensitivity was 124.7 cm. The ESD 50% fire voltage was 12.841 kV and 2.515 J, respectively. This indicated that (AT)(NTO) is thermally stable and relatively insensitive to impact, friction, and spark.

#### 8.8.4 3-Azido-1,2,4-triazole

3-Azido-1,2,4-triazole, CAS RN [35038-46-1] reacts with electrophiles [272]. Syntheses of five different azido-1,2,4-triazole derivatives were carried out starting with triaminoguanidinium chloride and a carboxylic acid (formic, acetic, 2,2,2-trifluoroacetic, 2-benzylacetic, monochloroacetic acid) via a three-step synthetic route [273]. The thermal decomposition of five different azido-1,2,4-triazoles was studied theoretically by using CHETAH and T1 software, and experimentally by using DSC to obtain kinetic data. Numerical modeling and mass spectrometry were also performed to estimate the nature of the intrinsic molecular reactivity and the possible early stages of a self-heating process.

Silver, copper(I), copper(II), potassium, cesium, ammonium, hydrazinium, guanidinium, and aminoguanidinium salts of 5-(5-azido-1*H*-1,2,4-triazol-3-yl)-tetrazol-1-ol were prepared and characterized by IR and multi-nuclear ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ) NMR spectroscopy, mass spectrometry, and DSC [274]. The metal salts were very sensitive while the nitrogen-rich salts were mostly insensitive. The metal salts were tested for their suitability as primary explosives.

3-Azido-1,2,4-triazole can be used as a starting product for the synthesis of other energetic materials and can be alkylated, halogenated, and complexed with metals, and converted to salts [275]. The azido group can also be carried at the end of an ethyl group instead of being directly attached to the ring [276].

#### 8.8.5 3-Nitramino-1,2,4-triazole

3-Nitramino-1,2,4-triazole, *N*-(1*H*-1,2,4-triazol-3-yl)nitramide,  $\text{C}_2\text{H}_3\text{N}_5\text{O}_2$ , CAS RN [34815-01-5],  $M = 129.084 \text{ g/mol}$ , is an energetic compound capable of forming salts. The enthalpy of formation of 3-nitramino-1,2,4-triazole is  $+112 \text{ kJ/mol}$  ( $+26.87 \text{ kcal/mol}$ ) [250].

3-Nitramino-1,2,4-triazole

The thermal destruction of *C*- and *N*-nitramino-substituted polynitrogen heterocycles, which are capable of tautomeric conversion, proceeds most likely through the thermochemically least stable nitramine form, as predicted by DFT calculations [277]. It was determined that the thermal destruction of *C*- and *N*-nitramino-substituted polynitrogen heterocycles, which are capable of tautomeric conversion, was most likely through the thermochemically least stable nitro- or nitramine form. Thermal decomposition of the considered tautomers is preferred at the  $\text{NNO}_2$  fragment and not at the triazole ring. The direction of the structural stabilization of the investigated

compounds has been clarified by comparison of the geometric, electronic, and thermochemical characteristics of C—NNO<sub>2</sub>- and N—NNO<sub>2</sub>-substituted 1,2,4-triazoles.

3-Nitramino-1,2,4-triazole (as the hydrate) was one of the many energetic compounds synthesized and used to make metal salts that are potentially useful as coloring agents in pyrotechnic formulations, replacing the environmentally damaging use of chlorates or perchlorates [278]. 3-Nitramino-1,2,4-triazole monohydrate, C<sub>2</sub>H<sub>5</sub>N<sub>5</sub>O<sub>3</sub>, with a molecular mass of 147.093 g/mol and an oxygen balance of −38.1%, melted at 365 K (92 °C) with loss of water and started to decompose at 488 K (215 °C). The anhydrous 3-nitramino-1,2,4-triazole, C<sub>2</sub>H<sub>3</sub>N<sub>5</sub>O<sub>2</sub> with a molecular mass of 129.078 g/mol and an oxygen balance of −43.1%, melted at 491 (218 °C). The heat of combustion was 2565 cal/g.

Triazolium or triazolate salts that contain both nitroamino and azido groups had not been well investigated until 2011. 3-Azido-*N*-nitro-1*H*-1,2,4-triazol-5-amine (which could also be called 3-azido-5-nitramino-1*H*-1,2,4-triazole or *N*-(3-azido-1*H*-1,2,4-triazol-5-yl)nitramide) was prepared by the selective nitration of guanazine, followed by heating at approximately 373 K (100 °C) for 1 h.

It decomposes at 416 K (143 °C), has a density of 1.79 g/cm<sup>3</sup>, and has an enthalpy of formation of 637 kJ/mol. 3-Azido-*N*-nitro-1*H*-1,2,4-triazole-5-amine was selected as the parent compound to become the anion in a series of salts that were prepared and examined. The proton on the nitramino N-atom is acidic. Twelve energetic nitrogen-rich salts based on 3-azido-*N*-nitro-1*H*-1,2,4-triazol-5-amine were prepared and characterized by <sup>1</sup>H, <sup>13</sup>C NMR, IR, DSC, and elemental analysis [279]. The crystal structures of the neutral compound 3-azido-*N*-nitro-1*H*-1,2,4-triazole-5-amine and its triaminoguanidinium salt were determined by single-crystal XRD.

1-Nitroamino-1,2,3-triazole was synthesized and its zwitterionic structure was established using single-crystal XRD [280]. The calculated detonation properties for 4-nitroamino-1,2,4-triazole (*P*<sub>det</sub> = 33.4 GPa, *v*<sub>det</sub> = 8793 m/s) and 1-nitroamino-1,2,3-tri-

azole ( $P_{\text{det}} = 33.0 \text{ GPa}$ ,  $v_{\text{det}} = 8743 \text{ m/s}$ ) were comparable with RDX. A series of energetic salts based on either the 1-nitroamino-1,2,3-triazolate or the 4-nitroamino-1,2,4-triazolate anion were prepared and characterized by IR, NMR, elemental analyses, density, TGA, and DSC. The HOFs and detonation properties for these stable salts were calculated using Gaussian 03 and Cheetah 4.0. Comparison of the properties of the 1,2,3- and 1,2,4-triazolate salts indicated that while the 1,2,4-derivatives were more stable thermally, the 1,2,3-analogs invariably had higher HOFs. In contrast to its salts, 1-nitroamino-1,2,3-triazole is extremely shock-sensitive with an impact sensitivity of  $<1 \text{ J}$ . In addition to 4-nitroamino-1,2,4-triazole, there is also a 1,2,4-triazole that contains two nitramino groups instead of only one. It forms triazolate salts with many inorganic (hydrazine) or organic amine bases.

Hydrazinium 3,5-dinitroamino-1,2,4-triazolate (HDNAT) was synthesized via condensation, nitrification, and hydrazinolysis reactions with a total yield of 63% [281]. Its structure was characterized by  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, FTIR, and elemental analysis. Its density is  $1.89 \text{ g/cm}^3$ , it has a melting point of  $467\text{--}469 \text{ K}$  ( $194\text{--}196^\circ\text{C}$ ), friction sensitivity of 92%, impact sensitivity of  $\text{H50 } 26.8 \text{ cm}$ , detonation velocity of  $9000 \text{ m/s}$  ( $\rho = 1.80 \text{ g/cm}^3$ ), and a detonation pressure of  $36 \text{ GPa}$ .

The 1-amino-2-nitroguanidinium 4-nitroamino-1,2,4-triazolate salt was synthesized using 1-amino-2-nitroguanidine and 4-nitroamino-1,2,4-triazole as the starting materials and its preparation reaction conditions were optimized [282]. The thermal decomposition behavior was investigated by TGA-DSC and its detonation properties were predicted using the Kamlet-Jacobs (K-J) equation. The yield of 1-amino-2-nitroguanidinium 4-nitroamino-1,2,4-triazolate salt was 86.5% under the optimum synthetic conditions (with a reaction time of 4 h and a reaction temperature of  $323 \text{ K} = 50^\circ\text{C}$ ). The compound decomposed sharply around  $448 \text{ K} = 175^\circ\text{C}$ . The HOF of the compound obtained by the Born-Haber cycle was  $551.3 \text{ kJ/mol}$ . The density is  $1.59 \text{ g/cm}^3$ . Based on the HOF and density obtained, the predicted detonation velocity and detonation pressure of the compound are  $8.05 \text{ km/s}$  and  $26.6 \text{ GPa}$ , respectively.

### 8.8.6 Nitro-1,2,4-triazoles

The nitro group can be attached to the 1,2,4-triazole ring either in the 2, (=4) or 3 (=5) position. In the 3- or 5-position, the molecule would contain a  $\text{C}-\text{NO}_2$  group. In the 2- or 4-position it would be a cyclic nitramine. Already small structural differences may affect the explosive properties of energetic materials to a great extent. This was demonstrated in the case of a series of 19 related compounds which all belonged to the group of nitrotriazoles and exhibited more or less distinctly different explosive properties [283]. Seven of these had been synthesized for the first time and are described in this publication. All compounds were characterized by IR, NMR, impact sensitivity, and friction sensitivity. Properties of several of these compounds are summarized in Table 16.

A summary of various methods for the properties and synthesis of nitro-1,2,3-triazoles is provided in [284]. The nitroazole derivatives discussed up to here are only

**Table 16:** Properties of nitrotriazole derivatives.

| Compound name                                                      | Density           | Enthalpy<br>of<br>formation | Explosion<br>temperature |      | Friction<br>sensitivity |      | Drop<br>weight<br>sensitivity |

Data source: [283].

a small sample of the many nitroazole compounds that have found industrial applications. An entire book has been devoted to nitrotriazoles, their synthesis, structures, and applications [285]. This monograph gives an exhaustive and systematic description of the methods of synthesis, application, structure, and properties of nitroazoles as components of high-energy materials and other applications. All five-membered ring nitro derivatives of azoles (pyrazoles, imidazoles, triazoles, tetrazoles, oxazoles, isoxazoles, oxadiazoles, thiazoles, isothiazoles, and thiadiazoles) were included, as were their benzanalogs (indazoles, benzimidazoles, benzoxazoles, benzisoxazoles, benzoxadiazoles, benzothiazoles, benzoisothiazoles, benzothiadiazoles, and benzo-triazoles). Several of these compounds are used for medicinal purposes.

Quantum chemical calculations were used to predict the BDE of seven nitrotriazole derivatives [286]. It was noted that the BDE of the initial scission step is be-

tween 184 and 293 kJ/mol (44 and 70 kcal/mol), which are larger than those of piperidine and diazocine compounds and polynitro benzoate molecules. Substituent groups greatly affected the BDE of these compounds. The HOFs for seven energetic materials were calculated via designed isodesmic reactions. It was noted that substituent groups strongly affect the HOFs. It was demonstrated that the HOF of compounds substituted by a five-membered ring is larger than those substituted by a six-membered ring for 1,2,4-triazole.

*N*-Trinitroethylamino energetic derivatives were obtained by carbon and nitrogen functionalization of nitropyrazoles and nitrotriazoles with nitroalkyl groups [287]. *N*-Trinitroethylamino nitroazoles and *N*-amino nitroazoles were characterized by IR, NMR, XRD, and elemental analyses. *N*-Functionalized nitroazoles have moderate to excellent thermal stabilities with good densities. Data based on impact and friction tests showed that these compounds ranged from very sensitive to insensitive and have good to excellent detonation pressures and velocities.

3-Nitro-1,2,4-triazole, with a well-known crystal structure [288], was one of the many energetic compounds synthesized and used to make metal salts that are potentially useful for colored pyrotechnic formulations, replacing the historical use of chlorates or perchlorates [278]. 3-Nitro-1,2,4-triazole, Compound No. (**12**),  $C_2H_2N_4O_2$ , which has a molecular mass of 114.063 g/mol and an oxygen balance of  $-42.1\%$ , melted at 488 K (215 °C), and started to decompose at 567 K (294 °C). The heat of combustion was 2388 cal/g.

Different nitroazole isomers based on five-membered heterocyclics were designed and investigated using computational chemistry to explore the relationships between the structure and performance of such high-nitrogen compounds [289]. Electronic structures of the molecules have been calculated using DFT and the HOF has been calculated using an isodesmic reaction approach. All designed compounds showed high positive HOF due to the high nitrogen content and energetic nitro groups. The crystal densities of these energetic azoles have been predicted with different force fields. All the energetic azoles had densities higher than 1.87 g/cm<sup>3</sup>. Detonation properties of energetic azoles were evaluated by using the K-J equation based on the calculated densities and HOFs. The energetic nitroazoles had a predicted detonation velocity of about 9.0 km/s and a detonation pressure of 40 GPa. The stability of the designed compounds was predicted by evaluating the BDE of the weakest C–NO<sub>2</sub> bond.

## 8.9 Di-Substituted 1,2,4-Triazole Derivatives

The HOFs ( $\Delta H_f^\circ$ ) in the gas phase of 1,4-dinitro-1,2,3-triazole and 1,3-dinitro-1,2,4-triazole were theoretically investigated by employing DFT and isodesmic reactions [156]. A correlation was developed between impact sensitivity h50% and the defined

sensitivity index. Based on this empirical relationship the impact sensitivities of new compounds, for which experiments were not available, were extrapolated.

### 8.9.1 3,5-Diamino-1,2,4-triazole

3,5-Diamino-1,2,4-triazole, 1*H*-1,2,4-triazole-3,5-diamine,  $C_2H_5N_5$ , CAS RN [1455-77-2] (also referred to as guanazole or guanozole), is a useful ingredient in gas generants and ionic liquids and is commercially available. 3,5-Diamino-1,2,4-triazole has a molecular mass of 99.09 g/mol and melts at 478 K (205 °C) (decomp.). The density of 3,5-diamino-1,2,4-triazole was predicted to be  $1.686 \pm 0.06$  g/cm<sup>3</sup>. It forms complexes with many transition metal salts.

The mid and far FTIR and FT-Raman spectra of 3,5-diamino-1,2,4-triazole were measured in the condensed state and compared to predicted spectra calculated using quantum chemical calculations [290]. The fundamental vibrational frequencies were calculated under different possible symmetries by a DFT method. The results of the calculations obtained (assuming *C*<sub>2</sub> symmetry) produced a global minimum on the potential energy surface. The vibrational spectra were interpreted with the aid of normal co-ordinate analysis based on scaled density functional force field theory. Alkylation of 3,5-diamino-1,2,4-triazole can occur either on the ring or on the amino groups [291].

The oxidation of 3,5-diamino-1,2,4-triazole occurs in two steps, with substantial differences in the rates of the first and second stages of oxidation yielding 5-amino-3-nitro- and 3,5-dinitro-1,2,4-triazole and allows isolation of the intermediate in up to 60% yield [292].

### 8.9.2 3,5-Dinitro-1,2,4-triazole

3,5-Dinitro-1,2,4-triazole, 3,5-dinitro-1*H*-1,2,4-triazole, DNTz,  $C_2H_1N_5O_4$ , CAS RN [26621-32-9], *M* = 159.06 g/mol, has a density of 2.042 g/cm<sup>3</sup> and an enthalpy of formation of +167 kJ/mol (+40.0 kcal/mol = +251 cal/g).

3,5-Dinitro-1,2,4-triazole can be prepared from 3,5-diamino-1,2,4-triazole (guanazole, DAT), with sulfuric acid and excess sodium nitrite [293]. The ammonium salt of 3,5-dinitro-1,2,4-triazole (ADNT) is an explosive with interesting properties. It is quite soluble in water (28 g/100 mL), has a calculated *P*<sub>CJ</sub> of 262 kbars at its crystal density of 1.632 g/cm<sup>3</sup>, melts with loss of ammonia at 443 K (170 °C), and has ERL Type 12/12B drop-weight impact sensitivities of 59/80 cm. It can be separated from the reaction mixture by solvent extraction [294].

3,5-Diamino-1,2,4-triazole was converted into 3,5-dinitro-1,2,4-triazole by diazotization with excess sodium nitrite. An alternate procedure was proposed for preparing 3,5-dinitro-1,2,4-triazole from dicyanodiamide and hydrazine without isolation of 3,5-diamino-1,2,4-triazole intermediate [295].

A pulsed laser-based photoacoustic pyrolysis technique using a Q-switched Nd:YAG laser at 532 nm with 7 ns duration pulses at 10 Hz repetition rate was used to

study the thermal stability of 1*H*-1,2,3-triazole derivatives with one to several nitro groups in the range 303–523 K (30–350 °C) [296].

The structural-kinetic laws of thermal decomposition in the solid phase of 3-nitro-1,2,4-triazole, bis(3-nitro-1,2,4-triazole-5-yl), and bis(3-nitro-1,2,4-triazole-5-yl)methane with melting points of 484.6, 510.6, and 581 K (211.5, 237.5, and 308 °C), respectively, were studied to reveal the influence of the 5-functional substituent on the rate and activation parameters of these compounds. The study also provided definitions of an eventual retarding effect of a crystal lattice (the ratio of decomposition rate constants in the liquid and the solid phase) [289, 297]. The gaseous decomposition products were analyzed by GC and MS. The condensed residue after decomposition was analyzed by IR. Thermal decomposition of these compounds in a temperature range 293–773 K (20–500 °C) proceeded in three stages. This was irrespective of the structure of the substance, where the exothermicities for first two compounds were thermoneutral. For the third compound, a heat emission was observed by DTA already at the first stage, accompanied by a smooth increase of an exothermic peak with a maximum at 551 K (278 °C).

3,5-Dinitro-1,2,4-triazole has a  $pK_a$  of  $-0.6$ , which indicates that it is a strong acid and thus it forms stable salts with many nitrogen bases. The CAS RN of the ammonium salt is [76556-13-3]. The assay of 1-ammonium-3,5-dinitro-1,2,4-triazole and its mixtures with ammonium nitrate (AN) can be determined by titration with cetylpyridinium chloride [298, 299].

### 8.9.3 3-Amino-5-nitro-1,2,4-triazole

3-Amino-5-nitro-1,2,4-triazole, 5-amino-3-nitro-1,2,4-triazole, 3-nitro-1*H*-1,2,4-triazol-5-amine, ANTA,  $M = 129.08$  g/mol,  $C_2H_3N_5O_2$ , CAS RN [58794-77-7] or [218787-12-3], can be prepared by an improved sequence where the dinitrotriazole salt is reduced with hydrazine, producing an almost quantitative conversion [300, 301]. ANTA melts at 513 K (240 °C) and has a density of  $1.820$  g/cm<sup>3</sup>.

3-Nitro-1-nitromethyl-1*H*-1,2,4-triazole

ANTA is very insensitive to impact and is moderately sensitive to thermal stimuli. Performance was found to be inferior to TATB. One of the best synthesis methods of ANTA is a three-step route using commercially available 3,5-diamino-1,2,4-triazole [302]. ANTA is being tested because it is an insensitive energetic material. The substituent combination of amino and nitro groups provides the inter- and intra-molecular hydrogen bonding that may stabilize the molecule and increase its density (see TATB). The heterocyclic structure is capable of adding density compared to the corresponding carbocyclic materials and in many cases contributes more to a positive HOF.

Nitrotriazoles are multi-purpose energetic materials. In this group, there are examples for all classes of explosives: primary explosives, insensitive high explosives (IHE), and gas generants. 3-amino-5-nitro-1,2,4-triazole (ANTA) can be converted into a new explosive with theoretically improved performance, a bitriazolyl compound [303]. Physical data and small-scale explosive properties of the new substances were summarized in this publication.

5-Amino-3-nitro-1*H*-triazole (ANTA) is a molecule with high thermal stability. Aside from being an IHE, it is also used as a synthon for other potential new energetic materials. The crystal structure of ANTA was resolved by XRD crystallography and two isomorphous crystal forms were found [304]. When ANTA was recrystallized from 2-butanone, crystals with molecular packing characterized by extended planar sheets were obtained ( $\beta$ -ANTA). The crystal density of  $\beta$ -ANTA is 1.73 g/cm<sup>3</sup>, which is less dense than that of  $\alpha$ -ANTA ( $\rho$  = 1.82 g/cm<sup>3</sup>). The crystal structure of  $\beta$ -ANTA, C<sub>2</sub>H<sub>3</sub>N<sub>5</sub>O<sub>2</sub>,  $M$  = 129.1 g/mol, was monoclinic with space group  $P2_1/n$ , and the unit cell parameters of  $a$  = 6.517(1) Å,  $b$  = 9.691(1) Å,  $c$  = 8.410(1) Å,  $\beta$  = 111.1°,  $V$  = 495.5(1) Å<sup>3</sup>,  $Z$  = 4, 1.730 g/cm<sup>3</sup>.

ANTA has more energy than NTO. It has a crystal density of 1.82 g/cm<sup>3</sup>, a positive HOF ( $\Delta H_f$ ) of +87.9 kJ/mol (+21.0 kcal/mol), and is thermally stable up to its melting point of 511 K (238 °C). The detonation velocity of ANTA was calculated at a crystal density higher than that of TATB and was predicted to be 8460 m/s, which is 7% higher than TATB.

The thermal stability of ANTA and that of six other explosives was measured by a TGA-MS combination using STMBMS. The results were compared to develop a kinetic model and to identify rate-determining steps [84].

The structure, tautomerism, and vibrational spectra of 3-amino-5-nitro-1,2,4-triazole molecule were studied by *ab initio* MO and DFT calculations, both in the gas phase and in solution [305]. It was found that in the gas phase, the most stable tautomer is 2*H*-ANTA (3-amino-5-nitro-1,2,4-2*H*-triazole) at one level, while at other levels the most stable tautomer is 1*H*-ANTA (3-amino-5-nitro-1,2,4-1*H*-triazole). For the 2*H*-ANTA tautomer, the calculated structures agreed well with the experimental X-ray structures. However, twisting of the nitro and amino groups were found to be much larger than in the solid state. The predicted IR spectra were given for all tautomers.

The results obtained for the dielectric constants  $\epsilon = 4.8, 18.5$ , and  $78.4$  suggested that, in a polar solvent, the most stable tautomer is *2H*-ANTA. This is in agreement with the existing experimental studies.

3-Amino-5-nitro-1,2,4-triazole and one of its derivatives have been prepared in order to carry out systematic studies on structural aspects, explosive performance, and thermal stability [306]. Thermal stability studies were carried out for ANTA and 4,6-bis-(3-amino-5-nitro-1*H*-1,2,4-triazole-1-yl)-5-nitropyrimidine (DANTNP) by TGA, DTA, DSC, and manometric thermal analysis. The results showed that DANTNP is thermally more stable than ANTA when compared in terms of activation energy.

5-Amino-3-nitro-1,2,4-triazole can be prepared by nitration of 5-acetamido-1,2,4-triazole, diazotization of 3-acetamido-5-amino-1,2,4-triazole, oxidation of guanazole and *N*-acylguanazole, or reduction of 3,5-dinitro-1,2,4-triazole [307]. Inelastic neutron scattering (INS) spectra were used to clarify the molecular and crystal structure of 3-amino-5-nitro-1,2,4-*2H*-triazole [308]. The experimental results were then compared to results from theoretical DFT calculations.

The thermal decomposition of 3-amino-5-nitro-1,2,4-triazole was examined using TGA-DTG-DTA and DSC techniques in the  $N_2$  atmosphere [309]. In the TGA, ANTA was found to decompose in two steps. The first step of mass loss was  $\sim 38\%$ , which corresponds to the removal of a  $NO_2$  group. The second step of thermolysis was due to the slow thermolysis of the residue, which can also be seen by the presence of two DTG peaks. Both DTA and DSC curves clearly indicated the exothermic nature of the first step of decomposition as there was an exothermic peak. The maximum of the DTA peak was at  $531\text{ K}$  ( $258^\circ\text{C}$ ) and the maximum of the DSC peak was at  $524\text{ K}$  ( $251^\circ\text{C}$ ). The second step of mass loss was slow and seemed to be somewhat exothermic. Just before the first exothermic peak, there was an endothermic peak in both the DTA (both under  $N_2$  as well as in air atmospheres) and DSC, which is due to the melting of ANTA (m.p.  $511\text{ K} = 238^\circ\text{C}$ ). Soon after melting, the compound decomposed, exothermically suffering a sudden weight loss. It was evident from simultaneous TGA-DTG-DTA plots that the compound suffered approximately  $95\%$  mass loss and only a very small amount ( $\sim 4.5\%$ ) of residue was left. The Arrhenius parameters of the isothermal decomposition were derived by 14 different methods and the activation energy ranged from  $53$  to  $62\text{ kJ/mol}$  with  $\ln$  of pre-exponential factors ranging from  $-6.6$  to  $-9.2$ . The activation energy derived from the time to explosion was  $48\text{ kJ/mol}$ .

ANTA forms a salt with hydrazine, which would also make a good propellant ingredient [310]. The compound forms orthorhombic crystals, space group *Pbca* with crystal lattice parameters of  $a = 5.392(2)\text{ \AA}$ ,  $b = c = 18.483(6)\text{ \AA}$ ,  $\rho = 1.612\text{ g/cm}^3$ ,  $V = 1327.1(7)\text{ \AA}^3$ ,  $Z = 8$ .

#### 8.9.4 3-Azido-5-amino-1,2,4-triazole

3-Azido-5-amino-1,2,4-triazole was obtained from 3,5-diamino-1,2,4-triazole in two ways. The first was by partial diazotization-substitution directly in the substrate or during its primary nitrosation. The second was with the use of direct or indirect protection of an amino group with subsequent conversion into an azido compound followed by deprotection [311].

#### 8.9.5 3-Hydrazino-4-amino-1,2,4-triazole

3-Hydrazino-4-amino-1,2,4-triazole (HATr) is a high-nitrogen compound (73.65% N) with good thermal stability. Its dihydrochloride can be prepared by reaction of tri-aminoguanidinium chloride with formic acid and with hydrochloric acid as catalyst under reflux conditions. Lithium hydroxide can then be used to neutralize the salt to obtain the free 3-hydrazino-4-amino-1,2,4-triazole [273]. It forms salts even with weak acids such as picric acid or 2,4,6-trinitroresorcinol [312]. From the DSC thermogram, the activation energy and the critical temperature for a thermal explosion for the two salts were calculated. The critical temperature for the thermal explosion of the picrate was 485 K and the critical temperature for the thermal explosion of the 2,4,6-trinitroresorcinol salt was 479 K.

#### 8.9.6 3-Nitro-1-nitromethyl-1H-1,2,4-triazole

3-Nitro-1-nitromethyl-1H-1,2,4-triazole,  $C_3H_3N_5O_4$ ,  $M = 173.10$  g/mol, crystallized in monoclinic, colorless plate crystal shapes, space group  $P2_1/c$ , and with the unit cell parameters of  $a = 6.6305(4)$  Å,  $b = 9.2888(3)$  Å,  $c = 10.9828(6)$  Å,  $\beta = 104.837(5)^\circ$ ,  $V = 653.87(6)$  Å<sup>3</sup>,  $Z = 4$ ,  $\rho_{XRD} = 1.758$  g/cm<sup>3</sup> at  $T = 293$  K [313]. The structure of 3-nitro-1-nitromethyl-1H-1,2,4-triazole is illustrated in Figure 7.

Molecular conformation analysis showed that the first stage of thermal decomposition is a breakage of the  $H_2C-NO_2$  bond. Activation parameters of the process were  $E_a = 172.6$  kJ/mol,  $\log A = 14.25$  [314].

Figure 7: 3-Nitro-1-nitromethyl-1*H*-1,2,4-triazole.

### 8.10 Tri-Substituted 1,2,4-Triazole Derivatives

One of the most frequently used tri-substituted triazoles serving as the starting point for the synthesis of energetic salts is 3,4,5-triamino-1,2,4-triazole (guanazine) [315]. Triaminotriazole is sensitive to air oxidation, which results in red-colored polyazoles.

4-Amino-3,5-dimethyl-4*H*-1,2,4-triazole or 3,5-dimethyl-4-amino-1,2,4-triazole can be prepared by reaction of acetonitrile with hydrazine hydrate. It crystallizes in prisms that melt at 469–472 K (196–199 °C). It is an intermediate in the synthesis of energetic compounds and ionic liquids.

1-Amino-3,5-dinitro-1,2,4-triazole (ADNT) can be made by amination of the sodium salt of 3,5-diamino-1,2,4-triazole (DNT- $\text{Na}^+$ ) with mesitylene sulfonyl hydroxylamine with a yield of 66% [316]. The DNT- $\text{Na}^+$  was obtained from 3,5-diamino-1,2,4-triazole. The structure of ADNT was characterized by IR, MS,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, and elemental analysis, and the thermal stability was studied by DSC. The melting and decomposition temperatures are 401.8 and 498.9 K (128.7 and 225.8 °C), respectively. The impact sensitivity (H50) with a 2-kg drop weigh is beyond 112 cm. This revealed that ADNT is an insensitive explosive with good performance. 4-Amino-3,5-dimethyl-1,2,4-triazole can be synthesized starting with hydrazinium hydrazinecarboxylate [317].

1-Amino-3,4-dinitro-1,2,4-triazole (ADNT) can be prepared by the amination of the parent anion with *O*-tosylhydroxylamine [318]. The prepared materials have been characterized chemically (XRD, NMR, IR, Raman) and as explosives (mechanical and electrostatic sensitivity). Their explosive performances can be calculated using the EXPLO5 computer code. Other 3,4,5-trisubstituted 1,2,4-triazoles can be prepared via *N*-acylamidrazone intermediates such as *N'*-acetyl-*N,N*-dimethylhydrazonamide or oxadiazole precursors [319].

The nitrate, perchlorate, dinitramide, azide, and 5-nitrotetrazolate salts of methylated 3,4,5-triamino-1,2,4-triazole-, 5-amino-1*H*-tetrazole-, 2-tetrazene-, and 1,1-dimethylhydrazine bases were prepared and their densities, melting points, onsets of exothermic decomposition, and heats of combustion were measured [320]. These energetic salts were prepared from the iodides by metathetical reactions with silver salts of the energetic anions. The insoluble silver iodide always precipitated. The enthalpies of formation of the energetic salts were calculated from the heats of combustion. Methylation decreased the sensitivities towards mechanical stimuli and increased the thermal and chemical stabilities of these salts.

#### 8.10.1 1-Methyl-3,5-dinitro-1,2,4-triazole (DNMT)

1-Methyl-3,5-dinitro-1,2,4-triazole,  $C_3H_3N_5O_4$ , CAS RN [1199-63-9], DNMT, MDNT, has been evaluated as a melt-cast binder, which is relative to TNT. It is an ideal “next generation” candidate, which would offer significantly improved performance and insensitivity over existing melt-cast binders [321]. Based on the melting point, calculated density, and perceived ease of preparation, DNMT is a good candidate for an insensitive explosive.

1-Methyl-3,5-dinitro-1,2,4-triazole

About 25 grams of the compound were prepared for characterization and small-scale safety evaluation. Based upon those results, the next phase envisioned a scale-up of up to 250 grams of material, with an eye toward optimization of the syntheses, obtaining sufficient material for Interim Hazard Classification (IHC), and Explosive (EX) classification tests, and somewhat larger scale safety and performance testing. In the

DSC, DNMT melted at 95 °C and began to decompose at 210 °C. Table 17 shows the impact sensitivity, friction sensitivity, and ESD test results of DNMT and RDX. The data reveals that DNMT is much less sensitive than RDX in these tests. The measured detonation velocity is 7850 m/s. This is nearly 99% that of Comp B but the C-J pressure is only 85% that of Comp B.

**Table 17:** Safety properties of DNMT in comparison to RDX.

| Compound abbreviation | ERL impact, cm | BAM friction, N | ESD, J |
|-----------------------|----------------|-----------------|--------|
| DNMT                  | >100           | >252            | >0.25  |
| RDX                   | 25.4           | >144            | >0.25  |

Data source: [321]

A high-performance liquid chromatography (HPLC) method was developed to analyze 1-methyl-3,5-dinitro-1*H*-1,2,4-triazole and the main impurity, 1-methyl-3-nitro-1*H*-1,2,4-triazol-5-amine [322]. 1-Methyl-3,5-dinitro-1*H*-1,2,4-triazole was detected by a UV-visible detector at 240 nm. The detection limits for 1-methyl-3,5-dinitro-1*H*-1,2,4-triazole and 1-methyl-3-nitro-1*H*-1,2,4-triazol-5-amine were 0.6 and 0.31 mg/mL, respectively. The method was shown to have a wide linear range, high sensitivity, and good reproducibility.

### 8.10.2 Polynitrotriazoles

1,2,4-Triazoles and azotriazoles containing one or two trinitromethyl groups were synthesized and characterized using IR and NMR spectroscopy, elemental analysis, DSC, and XRD [323]. The enthalpies of formation were calculated with Gaussian 03 and then combined with experimentally determined densities to calculate predicted detonation pressures and velocities of the energetic materials (Cheetah 5.0). They exhibited high density, good thermal stability, acceptable oxygen balance, positive HOF, and excellent detonation properties which were superior to those of TNT, RDX, and HMX in some instances. Examples of these are 5-nitro-3-(trinitromethyl)-1*H*-1,2,4-triazole,  $C_3HN_7O_8$ , and 5,5'-bis(trinitromethyl)-3,3'-azo-1*H*-1,2,4-triazole, (E)-bis[5-(trinitromethyl)-1*H*-1,2,4-triazol-3-yl]diazene, 3,3'-[(E)-1,2-Diazenediyl]bis-[5-(trinitromethyl)-1*H*-1,2,4-triazole],  $C_6H_2N_{14}O_{12}$ . The lone hydrogen on the triazole ring is acidic and allows the formation of salts with many bases.

3-Trinitromethyl-5-nitro-1,2,4-triazole

5,5'-Bis(trinitromethyl)-3,3'-azo-1H-1,2,4-triazole

Salts of trinitromethyl-substituted triazoles, 5-nitro-3-trinitromethyl-1H-1,2,4-triazole, and 5,5'-bis(trinitromethyl)-3,3'-azo-1H-1,2,4-triazole were synthesized and characterized using IR, NMR, elemental analysis, and DSC [230, 324]. Based on the HOFs calculated with Gaussian 03 and combined with experimentally determined densities, detonation properties of the energetic materials obtained with the EXPLO5 program identified them as potentially explosive compounds. They exhibited high density, moderate to good thermal stability, acceptable oxygen balance, reasonable HOF, and excellent detonation properties which were superior to those of RDX in some instances.

Three examples of 1,2,4-triazole and bi-1,2,4-triazole with trinitromethyl substitution were synthesized and characterized [325] including 3,3'-bistrinitromethyl-5,5'-bi-1H-1,2,4-triazole, which forms a solvate with diethyl ether:

Another compound synthesized was 5-nitro-3-trinitromethyl-1H-1,2,4-triazole. This compound had a density of 1.950 g/cm<sup>3</sup> and melted at 385.7 K (112.6 °C), followed immediately by a strong, exothermic decomposition. A trinitromethyl analog to NTO, where the nitro group has been replaced by a trinitromethyl group, gave an energetic compound with properties similar to NTO and improved oxygen balance. However, it had poor thermal stability. 3-trinitromethyl-1,2,4-triazol-5-one had a density of 1.885 g/cm<sup>3</sup> at 150 K and a very low onset of decomposition at 343 K (70 °C).

DFT methods were used to study the HOFs, electronic structure, energetic properties and pyrolysis mechanism of a series of trinitromethyl-substituted heterocyclic compounds, including triazole, tetrazole, furazan, tetrazine, and fused heterocycles [326]. It was found that the fused ring, tetrazine, and the tetrazole ring structures are effective structural units for increasing the HOFs of energetic materials. The substitution of the combination of nitro and trinitromethyl is very useful for improving their HOFs. The calculated energetic properties indicated that the combination of the nitro and trinitromethyl is very helpful for improving their detonation properties and oxygen balances. Most of the compounds studied in this work had a good oxygen balance above zero. An analysis of the BDE for several relatively weak bonds suggests that the N—O bond in the ring is a trigger bond for decomposition and the ring —NO<sub>2</sub> and (NO<sub>2</sub>)<sub>2</sub>C—NO<sub>2</sub> bond cleavage is likely to happen in thermal decomposition for other compounds.

The HOFs ( $\Delta H_f$ ) of various nitro-substituted azoles were predicted by orbital mechanics quantum chemical methods [327]. The overall mean absolute deviations and root-mean-square deviations of the predicted numbers were 2.0 and 2.6 kcal/mol, respectively, on the predictions of 48 known molecules. Overall, each additional nitrogen in the azole ring increased  $\Delta H_f$  by 10–30 kcal/mol. While the effect of the NO<sub>2</sub> substitution to carbon (C—NO<sub>2</sub>) was minor, that to nitrogen (N—NO<sub>2</sub>) increased  $\Delta H_f$

by 15–32 kcal/mol. Second-neighbor contribution can be significant for non-bonding interactions between NO<sub>2</sub> groups, which may increase  $\Delta H_f$  by 3–4 kcal/mol.

## 8.11 Other Triazole Compounds

### 8.11.1 Other Multi-Substituted Triazole Compounds

If the hydrogen atoms in triazoles or tetrazoles are replaced with nitrogen-containing energetic functional groups like the azido group or difluoroamino group, the enthalpy of formation of these compounds can be increased further. For example, the standard enthalpy of formation of 1,2,4-triazole increases from +109 to +458 kJ/mol if an azido group is introduced at the 3-position. The azidotriazole (and azidotetrazole) can form highly energetic salts with nitrate, perchlorate, 4,5-dinitro-imidazolate, or 5-nitrotetrazolate anions [328]. Quaternization of azidoalkyl-substituted 1,2,4-triazoles with 4,5-dinitroimidazole or 5-nitrotetrazole results in room-temperature liquids that may be useful in energetic materials/propellant applications [329, 330]. Similar salts are obtained from triazoles that carry both a methyl group and an azido group or triazoles that are substituted with an azidoethyl group.

Energetic salts were synthesized via the quaternization of azido or nitro derivatives of 1,2,4-triazole and substituted derivatives of tetrazole with nitric acid or perchloric acid or iodomethane. The first step reactions were followed by metathesis reaction with AgNO<sub>3</sub> or AgClO<sub>4</sub> to produce 1-(2-azidoethyl)-1,2,4-triazolium-5-nitrotetrazolate, 1-(2-azidoethyl)-3-azido-1,2,4-triazolium 5-nitrotetrazolate, 1-(2-azidoethyl)-4-amino-1,2,4-triazolium perchlorate and 1-(2-azidoethyl)-1,2,4-triazole [276]. These ionic liquid salts exhibited good thermal stabilities, low vapor pressure, high HOF, and high densities. Constant volume combustion energies and structures were determined experimentally using oxygen bomb calorimeter, DSC, and <sup>1</sup>H and <sup>13</sup>C NMR.

The nitrogen-rich energetic material 3,4,5-triamino-1-tetrazolyl-1,2,4-triazole (TATT) was synthesized from diaminoguanidine using a straightforward method [331]. The assumption that a 1,2,4-triazole ring is an intermediate in the one-pot reaction was supported by the synthesis of TATT from an analogous reaction of 3,4,5-triamino-1,2,4-triazole with cyanogen azide. TATT•HNO<sub>3</sub> crystallizes in the monoclinic system *P*2<sub>1</sub>/*c*. TATT has excellent thermal stability which resembles that of triaminotrinitrobenzene (TATB), but with a higher positive HOF and greater impact insensitivity.

### 8.11.2 Polymeric 1,2,4-Triazole Compounds

Energetic polymer salts from 1-vinyl-1,2,4-triazole derivatives have been synthesized via free radical polymerization of 1-vinyl-1,2,4-triazolium monomer salts or by protonation of poly(1-vinyl-1,2,4-triazole) with inorganic or organic acids [332]. Standard

enthalpies of formation of the monomer salts were calculated. Compared with the monomer salts, the polymer salts have good thermal properties with high densities  $\rho > 1.5 \text{ g/cm}^3$ .

Triazole and/or tetrazole-containing polymers would be of interest for solid rocket propellants. Interaction of cyanuric chloride and its mono- and di-chloro derivatives with ammonium or sodium 4-nitro-1,2,3-triazolates and polymer-analogous transformations of tetrazole-containing polymers were used to synthesize polynuclear systems and macromolecular compounds with heterocyclic structures bearing explosophoric groups [333].

1,2,3-Triazole crosslinked polymers were synthesized as a new binder for solid rocket propellant systems by reacting the azide groups of the polymer with the ethynyl groups of a dipolarophile curing agent [334]. The prepolymer mixtures were cured in an oven at 325 K (52°C) for 7 d. The progress of the curing reaction was monitored using an FTIR spectrometer. The carbonyl group adjacent to the  $\text{C}\equiv\text{C}$  triple bond, which acts as an EWG, considerably accelerated the 1,3-dipolar cycloaddition reaction between the azide and ethynyl functional groups, producing rubbery materials. The modulus of the polymers increased whereas the elongation at the break decreased with the increasing ratio of the crosslinker to the prepolymer, resulting in highly crosslinked polymers.

### 8.11.3 Fused Triazolo Ring Compounds

A benzene ring can carry up to three attached 1,2,3-triazole rings, forming a four-ring system called tris(1,2,3-triazolo)benzene or 5,8-dihydro-2*H*-bis[1,2,3]triazolo[4,5-*e*:4',5'-*g*]benzotriazole.

Tris(1,2,3-triazolo)benzene

Tris(triazolo)benzene was synthesized via 1,3,5-triaminobenzene and converted to its trinitro and trichloro derivatives ( $\text{R}=\text{NO}_2$ ,  $\text{Cl}$ ) [335]. The HOFs of these high-nitrogen compounds were calculated and combined with experimentally determined densities to establish detonation pressures and velocities. They exhibited high density, good thermal stability, high HOFs, and moderate to good detonation properties. Trinitrotris-(triazolo)benzene is not stable at room temperature and starts decomposing at 311 K (38°C). Its density is  $1.82 \text{ g/cm}^3$ , its HOF is  $+710 \text{ kJ/g}$ , the predicted detonation pressure

is 31.20 GPa, the detonation velocity is 8376 m/s, and its drop weight impact sensitivity is 3.0 J. As far as drop weight sensitivity is concerned, this was the most sensitive compound of the entire group investigated. The hydrogens on the triazole rings are acidic and can form ammonium salts.

#### 8.11.4 Bi-1,2,4-triazole Compounds

These compounds are commonly called bis-triazole although a more appropriate name would be bi-triazole. For instance, the compound formed by connecting two benzene rings is correctly called *biphenyl* and not *bisphenyl*. If two triazole rings are connected at the 4-position, the resulting bi-triazole (or bis-triazole) is a very energetic compound that can also form salts with strong acids [202, 336]. The melting points of these salts have already been stated in Table 76. A starting reactant for the synthesis of many other bitriazole derivatives is 3,3'-diamino-5,5'-bi-1,2,4-triazole. This can be made by reaction of oxalic acid and aminoguanidinium bicarbonate in concentrated hydrochloric acid at 343 K (70 °C) followed by isolation of the intermediate product by filtration. While heating to reflux in basic media, the molecule undergoes cyclization, which leads to the formation of 5,5'-diamino-bi-1,2,4-triazole.

Bi-1,2,4-triazoles connected through a C—C bond are expected to demonstrate similar energetic properties in comparison to azo-bridged 1,2,4-triazole compounds, also when comparing them to the outstanding properties of 5,5'-bitetrazoles. 5,5'-dinitro-3,3'-bi-1,2,4-triazole (DNBT) is a HEDM. The thermal stability of DNBT and that of six other explosives was measured by a TGA-MS combination using STMBMS. The results were compared to develop a kinetic model and were used to identify the rate-determining steps [84].

Bi-1,2,4-triazole was synthesized from *N,N*-dimethylformamide azine dihydrochloride and 4-amino-1,2,4-triazole in toluene as solvent [337]. The structure of bi-1,2,4-triazole was characterized by <sup>1</sup>H NMR, IR, MS, and elemental analysis. A single crystal of bis-1,2,4-triazole was also cultivated successfully and its crystal structure was determined by XRD. The crystal was an orthorhombic system, space group *Pnma* with crystal parameters of  $a = 0.69712(14)$  nm,  $b = 0.74045(15)$  nm,  $c = 1.1156(2)$  nm,  $V = 0.5759(2)$  nm<sup>3</sup>,  $Z = 4$ , and  $D_{\text{XRD}} = 1.570$  g/cm<sup>3</sup>. The two triazole rings in bis-1,2,4-triazole are oriented vertically to each other. This should be beneficial to the stability of the molecule due to the least steric hindrance.

There are substantially more publications on bistetrazoles and azotetrazoles than on bistriazoles and azotriazoles. Nevertheless, these compounds have been explored but they do not seem to offer any advantages over their tetrazole relatives.

The synthesis and full structural and spectroscopic characterization by XRD, IR, Raman, and multi-nuclear NMR spectroscopy of three asymmetrically substituted bi-1,2,4-triazoles, along with different energetic moieties like amino, nitro, nitrimino, and azido moieties, was done to study the influence of these energetic moieties on structural and energetic properties [263, 338]. A calculation of the standard enthalpies

of formation revealed highly positive HOFs and good detonation properties for all compounds. The measured sensitivities to mechanical stimuli and decomposition temperatures strongly depended on the energetic moiety of the triazole ring. The ionic derivatives were found to be thermally stable and insensitive compounds.

Substituents like nitroimino groups on both rings of bitriazole will increase the energy content of the molecule [339]. Bis[3-(5-nitroimino-1,2,4-triazolate)]-based energetic salts exhibited low solubility in available solvents, high hydrolytic stability, excellent thermal stability, high density, positive HOF, low shock sensitivity, and excellent detonation properties. The physical and energetic properties of some salts are similar and even superior to those of RDX.

Five symmetrical bi-1,2,4-triazoles, where both rings were carrying energetic substituents like amino, nitro, nitrimino, azido, and dinitromethylene groups, were synthesized and characterized [340]. The main objective was a comparative study on the influence of those energetic substituents on the structural and energetic properties of the resulting compound. A complete characterization included XRD, IR, Raman, and NMR spectroscopy of all compounds. The standard enthalpies of formation were calculated and the predicted detonation parameters were computed using the EXPLO5.05 program. The impact, friction, and ESD sensitivities were determined experimentally. The molar enthalpy of formation of 3,3'-dinitro-5,5'-bi(1*H*-1,2,4-triazole) is +285 kJ/mol, and that of 3,3'-diazido-5,5'-bi(1*H*-1,2,4-triazole) (DNBT) is +971 kJ/mol. The onset of decomposition of 3,3'-dinitro-5,5'-bi(1*H*-1,2,4-triazole) is 524 K (251 °C) and that of 3,3'-diazido-5,5'-bi(1*H*-1,2,4-triazole) is 474 K (201 °C). DNBT may also be described as 5,5'-dinitro-2*H*,2'*H*-3,3'-bi-1,2,4-triazole, where the location of the hydrogen atoms is identified. It has a very high density (1.903 g/cm<sup>3</sup>) and can form stable salts, preferably with nitrogen-rich bases. Highly nitrogen-rich salts of DNBT formed from ammonium, hydroxylammonium, hydrazinium, guanidinium, aminoguanidinium, and triaminoguanidinium cations were prepared and fully characterized by IR, Raman, NMR, DSC, and XRD [341]. The standard enthalpies of formation were calculated for selected compounds and the predicted detonation parameters were calculated. The impact, friction, and ESD sensitivity were also determined. One cannot help but wonder if “triazolide” anion should not be referred to as “triazolate” anion instead. Or is the anion ending with “ate” reserved only for oxygen-containing anions?

### 8.11.5 Azo-1,2,4-triazole Compounds

Two triazole rings can be connected either directly via a C—C bond as in bitriazole or via an azo —N=N— group (as in azotriazole). The conjugation of the electron cloud extends from one ring to the other, thus stabilizing the molecule. Azo-bridged triazoles (mainly 1,2,4-triazoles) are high nitrogen compounds as well as HEDM [342]. Azotriazole can form azotriazolium salts. Instead of being connected directly by a C—C or N—N bond, the two triazole rings in azotriazole are connected via an azo —N=N—bridge.

This actively participates in the resonance structure of the aromatic system. The connection to the ring can be at the 1-, 3- or 4-position. Azotriazoles are also called azobistriazoles but the *bis* prefix is unnecessary. Azobenzene does not use the *bis* prefix either.

1,1'-Azo-1,2,4-triazole

4,4'-Azo-1,2,4-triazole

1,1'-Azo-1,2,4-triazole contains a chain of six nitrogen atoms and is unsymmetrical while 4,4'-azo-1,2,4-triazole has only four nitrogen atoms in line and is symmetrical along the N=N axis of the azo group.

5,5'-Dinitro-3,3'-azo-1,2,4-triazole, 3,3'-dinitro-5,5'-azo-1*H*-1,2,4-triazole, 3,3'-azobis(5-nitro-1*H*-1,2,4-triazole),  $C_4H_2N_{10}O_4$ , DNAT, CAS RN [140218-61-7],  $M = 254.13$  g/mol, has a density of  $1.88$  g/cm<sup>3</sup> and has a HOF of  $+406$  kJ/mol ( $+97$  kcal/mol). DNAT is a strong acid and forms salts with many bases. Based on XRD crystallography data, 1,1'-dinitro-3,3'-azo-1,2,4-triazole (N-DNAT) exists in two polymorphic forms [343]. The yellow color polymorph has a crystal density of  $1.701$  g/cm<sup>3</sup>, while the density of the orange crystal is  $1.831$  g/cm<sup>3</sup>.

3,3'-Dinitro-5,5'-azo-1*H*-1,2,4-triazole (DNAT)

The high-nitrogen molecule, 5,5'-dinitro-3,3'-azo-1,2,4-triazole, (3-nitro-3*H*-1,2,4-triazol-5-yl)-(5-nitro-3*H*-1,2,4-triazol-3-yl)diazene, DNAT, was calculated to have a high density and a positive enthalpy of formation [304]. In an attempt to prepare DNAT via the oxidation of ANTA with different oxidizers, it was found that DNAT was the reaction product when the potassium salt of ANTA was oxidized with potassium permanganate. However, when ANTA was oxidized with ammonium persulfate in an aqueous medium, one of the reaction products obtained was the azoxy molecule of DNAT (DNATzT). It was not possible to determine the crystal densities of either

DNAT or DNAzT because the crystals obtained were solvated with the crystallization solvents.

The solid-state structure of 4,4'-azobis(1,2,4-triazole) was determined by XRD [344]. The experimentally determined density and enthalpy of formation matched with theoretically computed values based on the B3LYP method. Based on DSC results, 4,4'-azobis(1,2,4-triazole) decomposed at a relatively high temperature (586 K = 313 °C). By comparison with 3,3'-azobis(1,2,4-triazole), which contains a C=N=N-C'-azo linkage, the N,N'-azo linkage was found to provide compounds with a relatively high density and high energy.

3,3'-Dinitro-5,5'-azo-1*H*-1,2,4-triazole (DNAT) was synthesized by the oxidative coupling of 5-amino-5-nitro-1,2,4-triazole (ANTA) as raw material [345]. Its structure was characterized by IR, NMR, and elemental analyses.

The drop weight impact sensitivity  $H_{50}$  of DNAT was 17.08 cm (drop-hammer mass 5 kg) and the friction sensitivity of 60% initiation was 3.92 MPa pressure at a pendulum angle of 90°. Single crystals of DNAT•4H<sub>2</sub>O were grown from solutions, and the crystal structure was determined by XRD to be monoclinic with space group  $P_2(1)/n$  and a density of = 1.550 g/cm<sup>3</sup>.

DNAT and its triaminoguanidinium salt were characterized for thermal stability and detonation and strand burning behavior [346–349]. The triaminoguanidinium salt of DNAT, TAGDNAT, can be easily synthesized through neutralization by treatment of DNAT with sodium hydroxide, followed by cation metathesis with triaminoguanidinium chloride.

The reaction was performed in water and the product was isolated in excellent yield as a yellow crystalline solid. The material was found to have a thermal decomposition onset temperature of 478 K (205 °C), using a 10 °C/min heating ramp rate. The energy released upon decomposition was 1681 J/g. The HOF of TAGDNAT was measured using combustion calorimetry. Based on the values for the heat of combustion for TAGDNAT, a HOF of +711 kJ/mol was determined. In comparison, the HOF of DNAT itself was reported to be 406 kJ/mol. Similar reactions were performed with the *N*-oxide of DNAT. TAGDNAT was formulated with 5% KEL-F binder and pressed into cylindrical pellets (1.27 × 1.27 cm) of 94% theoretical maximum density and tested for detonation velocity and constant-pressure strand burn rates. The measured detonation velocity and

estimated detonation pressure of TAGDNAT pellets were compared with and closely matched the predicted values calculated using the Cheetah 5.0 code. The burning rate function was  $r_b = 0.799p^{0.507}$ . Additional information on TAGDNAT may be found in the section on TAG salts (*Encyclopedia of Liquid Fuels*, chapter “Amides and Imides”).

1,1'-Azobis-1,2,4-triazole, 1,1'-azobis-(3-nitro-1,2,4-triazole), or 1,1'-azobis-(3,5-dinitro-1,2,4-triazole) can be prepared by oxidizing the corresponding amine with *tert*-butyl hypochlorite [350]. Azo-bridged azole derivatives were designed and investigated to find a comprehensive relationship between the structure and performance of nitrogen-rich energetic compounds [351]. DFT calculations were used to predict optimized structures, HOF, and detonation properties. The nitroazoles showed higher densities than amino and azido derivatives and hence better detonation performance. Thermal stability was analyzed using BDE of C—NO<sub>2</sub>, C—NH<sub>2</sub>, and C—N<sub>3</sub> bonds. The amino derivatives were found to be more stable and less sensitive than the nitro or azido compounds.

A new family of high-nitrogen compounds – that is, polyazido- and polyamino-substituted *N,N'*-azo-1,2,4-triazoles – were synthesized and fully characterized [352]. The structures of 3,3',5,5'-tetra(azido)-4,4'-azo-1,2,4-triazole and 3,3',5,5'-tetraamino-4,4'-azo-1,2,4-triazole were confirmed by XRD and thermal stability was determined by DSC. Their HOF and density, which were calculated by using a Gaussian 03 method, were used to predict the detonation performances of the related compounds using EXPLO 5.05. The HOFs of the polyazido compounds were also derived by using an additive method. 3,3',5,5'-tetra(azido)-4,4'-azo-1,2,4-triazole had the highest HOF (6933 kJ/kg) reported so far for energetic compounds and a detonation performance that is comparable to that of HMX, while 3,3',5,5'-tetra(amino)-4,4'-azo-1,2,4-triazole had a predicted onset of decomposition temperature of up to 563 K (290 °C).

*N*-diazo-bridged azoles were synthesized based on oxidative coupling of *N*-aminoazoles [353]. The incorporation of extended catenated nitrogen-atom chains with nitro groups led to compounds with favorable functional compatibilities. This combination was the basis for a series of high-density energetic materials (HEDMs) with high HOFs, enhanced densities, positive oxygen balances, and good detonation properties while retaining excellent thermal stabilities and relatively low impact sensitivities. Calculated and experimental studies showed the delicate balance between the length of the nitrogen atom chain and the energetic performance and stability, thus providing a promising strategy for designing advanced energetic materials.

A series of derivatives of *N,N'*-azobis(1,2,4-triazole) substituted by —N<sub>3</sub>, —NO<sub>2</sub>, —NF<sub>2</sub>, and —NH<sub>2</sub> groups was studied using the DFT method [354]. Strong  $p-\pi$  and  $\pi-\pi$  conjugation interactions exist in these molecules. Substituent effects on the geometrical and electronic structures, the aromaticity of the triazole ring, electronic sensitivity, impact sensitivity, thermal stability, density, solid-state HOF, detonation velocity, detonation pressure, and specific impulse were investigated. Substituent groups had significant and differing effects on performance: —N<sub>3</sub>, —NF<sub>2</sub>, and —NO<sub>2</sub> groups are

very helpful for enhancing explosive performance but the opposite occurs for the  $\text{—NH}_2$  group. The order of the contribution of various groups to explosive performance was  $\text{—NF}_2 > \text{—NO}_2 > \text{—N}_3 > \text{—NH}_2$ .  $\text{—NO}_2$  results in the second-highest explosive performance and the best electronic stability.  $\text{—N}_3$  gives relatively low explosive performance and stability but the highest  $\Delta H_f$  and specific impulse.  $\text{—NH}_2$  leads to the lowest explosive performance while providing the best impact and thermal stability.

Nitrogen-rich energetic salts based on 3,3'-diamino-4,4'-azo-1,2,4-triazole containing an N,N'-azo linkage have been synthesized and fully characterized by IR,  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra, elemental analysis, DSC and sensitivities toward impact, and friction and electrostatic discharge [355]. The crystal structures of the chloride, nitrate, and perchlorate salts have been determined by single-crystal XRD. All the salts exhibited high thermal stabilities with decomposition temperatures over 473 K (200 °C) except for the nitroformate salt. The densities of the salts were in the range of 1.71 to 1.99 g/cm<sup>3</sup>.

Azo-bis-1,2,4-triazole acts as an excellent backbone for the synthesis of energetic compounds owing to its characteristics such as high enthalpy of formation, high nitrogen content, and plane structure [356].

## 8.12 Triazolium and Triazolate Salts

The pK of an amine base is usually a good indication of how easily the amine can be protonated. The pK of 4-amino-1,2,4-triazole is 2.25, that of 1,2,4-triazole is 10.04, and that of 1,2,3-triazole is 8.2. All three triazoles form salts with mineral acids that have interesting properties as ionic liquids. In particular, the salts with oxidizing mineral acids such as nitric, perchloric, and dinitramidic acid are of interest as potential rocket propellants. The melting points of 1,2,3-triazolium salts are lower than those of their 1,2,4-triazolium isomers. Even lower melting points can be achieved with highly unsymmetrical mono- or poly-substituted triazolium salts. The physical properties of triazolium salts are summarized in Table 18. The perchlorates are the most stable and the dinitramides are the least stable triazolium salts. All are potentially explosive and some are very friction sensitive [357–360]. The IR, Raman, and NMR spectra of the various salts were measured. Only the 1,2,4-triazolium perchlorate was crystallized well enough that a single crystal could be used for the determination of its crystal structure by XRD.

The EILs formed by the 1,2,4-triazolium cation family and dinitramide anion were investigated by *ab initio* quantum chemistry calculations. This was to address the following questions: How does the substitution at the triazolium ring's nitrogen atoms affect its HOF and its charge delocalization? What kind of ion dimer structures might exist? And, do deprotonation reactions occur, as a possible first step in the decomposition of these materials [361]? (see also [328]).

**Table 18:** Physical properties of unsubstituted and substituted 1,2,3- and 1,2,4-triazolium salts.

| Parent amine                  | Anion                                         | Melting point    |                  | Decomposition temperature |         | Density<br>g/cm <sup>3</sup> | Standard enthalpy of formation (calculated) |          | Impact sensitivity, kg-cm (2-kg weight) |
|-------------------------------|-----------------------------------------------|------------------|------------------|---------------------------|---------|------------------------------|---------------------------------------------|----------|-----------------------------------------|
|                               |                                               | K                | °C               | K                         | °C      |                              | kJ/mol                                      | kcal/mol |                                         |
| 1,2,4-Triazole                |                                               |                  |                  |                           |         |                              |                                             |          |                                         |
|                               | NO <sub>3</sub> <sup>−</sup>                  | 410              | 137              | 433–455                   | 160–182 | 1.64                         | −42.7                                       | −10.2    | >200                                    |
|                               | ClO <sub>4</sub> <sup>−</sup>                 | 362              | 89               | 558                       | 285     | 1.96                         | −1.3                                        | −0.31    | 114                                     |

Data sources: [2, 201, 325, 359, 362].

Ionic liquids are discussed in this volume in the chapter “Ionic Liquids.” Similar properties can be observed with aminotriazoles where the amino group can be attached to a nitrogen or a carbon atom in the ring. The most common aminotriazole is the 4-amino-1,2,4-triazole.

1,2,3-Triazolium salts have been known for a long time. However, their potential as ionic liquids and catalysts was recognized only two decades ago. 1,2,3-Triazolium ionic liquids can serve as solvents, catalysts, hosts in anion recognition, and as energetic materials [363]. One application involves tethering catalytically active species such as (S)-proline with triazolium ionic liquids and using this as an anion-recognizing organocatalyst. Such catalysts are interesting not only due to their recyclability but also because of their outstanding tunable properties. They can have a wide liquid range, thermal stability, tunable polarity, low flammability, tunable solubility, and low vapor pressure along with ease of separation. The syntheses of 1,2,3-triazolium salts are mainly based on the copper-catalyzed azide-alkyne cycloaddition as the most practical click reaction and subsequent *N*-alkylation of the resulting 1,2,3-triazoles. This synthetic route has the advantage of having four structural units, i.e., the alkyne, the azide, the alkylating agent, and the counter anion that can be varied in order to tune the properties of the resulting ionic liquid. Unlike the imidazolium ionic liquids, 1,2,3-triazolium salts do not have an acidic proton at position two, which could make them inappropriate for reactions under basic conditions. The low acidity of 1,2,3-triazolium salts in position four can be exploited in the formation of 1,2,3-triazol-4-ylidene metal complexes with marked catalytic properties (see also [364]).

### 8.12.1 Physical and Chemical Properties of 1,2,4-Triazolium Salts

The nitrate, perchlorate, and dinitramidate salts of 1*H*-1,2,4-triazole, 4-amino-1,2,4-triazole, 3,4,5-triamino-1,2,4-triazole (“guanazine”), and 1*H*-1,2,3-triazole were synthesized and characterized for their sensitivity [357, 365]. XRD study of 1,2,4-triazolium perchlorate showed significant hydrogen bonding between the perchlorate anion and the triazolium ring, which contributes to its relatively high density of 1.96 g/cm<sup>3</sup>. The nitrate salt of 3,4,5-triamino-1,2,4-triazole melted at 478 K (205 °C), the perchlorate salt at 469 K (196 °C), and the dinitramidate salt at 418 K (145 °C). The onset of exotherm in the DSC was 523 K (250 °C) for the nitrate, above 573 K (300 °C) for the perchlorate, and 423 K (150 °C) for the dinitramidate salt. In the thermal stability test at 348 K (75 °C), the mass loss rate was less than 1%/day for several days. The friction and impact sensitivity was less than that of HMX. Two of the salts of 4-amino-1,2,4-triazole, m.p. 394 K (121 °C) had melting points lower than the parent amine. The melting points were 410 K (137 °C), 362 K (89 °C), and 348 K (75 °C) for the nitrate, perchlorate, and dinitramidate, respectively. 1*H*-1,2,3-triazole is a liquid at room temperature, but its salts were melting higher than the parent amine. The nitrate salt melted at 383 K (110 °C) with a DSC exotherm onset at 398 K (125 °C). The perchlorate salt melted at 346 K (73 °C) with an exotherm onset at 493 K (220 °C). The dinitramidate salt melted at 334 K (61 °C) with an

exotherm onset at 353 K (80 °C). When stored at 348 K (75 °C) for several days, only the perchlorate had a mass loss rate of less than 1%/d.

Many of these lower melting salts are ionic liquids [359, 362, 366, 367]. Additional information on ionic liquids can be found in *Encyclopedia of Liquid Fuels*, chapter “Ionic Liquids.”

The densities and enthalpies of formation of triazolium salts can be predicted using computational chemistry methods [368]. While it is relatively easy to predict enthalpies of formation of gaseous molecules, it is more difficult for crystalline or molten substances. A method has been derived from empirical density data to predict the cohesive energy from the molecular structure of ionic compounds [369]. Table 19 is a sample of energetic compounds for which densities were known.

Table 20 is a summary of properties of 1,2,4- and 1,2,3-triazolium nitrates, perchlorates, and dinitramides. 1*H*-1,2,4-triazole-copper complexes are of interest as gas generants. The thermal stability and ignition temperature of such complexes can be modified by substituting a ring hydrogen with an electrophilic or nucleophilic group.

Data source: [309].

The effects of a given substituent, its ability to supply/withdraw electrons to/from the reaction site on the properties of 1*H*-1,2,4-triazole-copper complexes were investigated [370]. The substituents were selected based on their Hammett constant value. Nitro group ( $-\text{NO}_2$ ), chloro group ( $-\text{Cl}$ ), and an amino group ( $-\text{NH}_2$ ) were selected as substituents, and 1*H*-1,2,4-triazole-copper complex, nitro-1*H*-1,2,4-triazole-copper complex, amino-1*H*-1,2,4-triazole-copper complex, and chloro-1*H*-1,2,4-triazole-copper complexes were synthesized and their thermal decomposition behaviors were investigated. According to SC-DSC measurements, the substituents can be used to control the thermal stability of 1*H*-1,2,4-triazole-copper complexes based on their electron donor/acceptor nature and their Hammett constant value.

Triazolyl-functionalized monocationic energetic salts were prepared through reactions of 1-(chloromethyl)-1*H*-1,2,4-triazole with 1-methylimidazole, 1-methyl-1,2,4-triazole, or 4-amino-4*H*-1,2,4-triazole in the presence of NaI, followed by metathetical reactions with equivalent silver salts [371]. Subsequent protonation with corresponding acids gave rise to triazolium-functionalized dicationic salts. Direct treatment of neutral 1-(1*H*-imidazole-1-yl)methylene-1*H*-1,2,4-triazole gave rise to the corresponding dicationic energetic salts. These were prepared by reaction of 1-(chloromethyl)-1*H*-1,2,4-triazole with imidazole in the presence of a base, with acids in methanol or metathesis with silver salts after quaternization with methyl iodide. All of the energetic salts were characterized by DSC, TGA, and density determinations. The majority exhibited good thermal stability and relatively high density. The synergistic effect of two energetic rings in cations and the effect of anions on their preparation and physicochemical properties were examined. The densities, standard enthalpies of formation, detonation pressures, detonation velocities, and specific impulse values for these unsymmetrical dicationic energetic salts were then calculated.

A series of functionalized imidazolium and 1,2,4-triazolium salts with cyanomethyl, vinyl, and propargyl substituents coupled with energetic anions such as perchlorate, nitrate, dicyanamide, and dinitramide were prepared and characterized by NMR, IR spectroscopy, and elemental analyses [181]. Since some of these salts melt  $<100^\circ\text{C}$ , they can be classified as ionic liquids. Their densities ranged between 1.25 and 1.76 g/cm<sup>3</sup>. The standard enthalpies of formation of the salts were calculated and ranged from  $\Delta H^\circ_f = -56$  to  $+851$  kJ/mol. Of all the salts synthesized, the dicyanamides exhibited the highest positive HOFs but also the lowest densities.

Joining a 1,2,4-triazole ring with a tetrazole ring such as in 1-(1*H*-1,2,4-triazol-3-yl)-1*H*-tetrazole gives a wide range of high-nitrogen compounds that can form salts with nitrogen-rich cations. The energetic salts of 1-(1*H*-1,2,4-triazol-3-yl)-1*H*-tetrazole, 5-(1*H*-tetrazol-1-yl)-1*H*-1,2,4-triazol-3-amine, 1-(3-azido-1*H*-1,2,4-triazol-5-yl)-1*H*-tetrazole, and 3-azido-1*H*-1,2,4-triazol-5-amine with various cationic moieties were prepared and their densities, HOFs, chemical energy of detonation, detonation velocities and pressures were calculated [372]. All of the compounds possessed high positive HOFs due to high energy contribution from the molecular backbone of the

corresponding compounds. Substitution with nitro, amino, and azido groups can improve their performance and/or stability.

Any combination of nitrogen-rich 1,2,4-triazole (**1**) and 1,2,3-triazole (**2**) bases with oxygen-rich acids  $\text{HNO}_3$  (a),  $\text{HN}(\text{NO}_2)_2$  (b), or  $\text{HClO}_4$  (c) produces energetic salts (1a, 1b, and 1c and 2a, 2b, and 2c, respectively). These are useful for composite explosives and propellants. The enthalpies of formation of these salts were studied with the dispersion-corrected DFT [373]. For the isomers such as 1a and 2a, the more negative  $\Delta G$  of the formation reaction leads to a thermally more stable salt. The ability to form intramolecular hydrogen bonds predicted with the quantum theory of atoms in molecules has the order of  $2 > 1$ . Different hydrogen bonds result in different second-order perturbation energies, redshifts in IR, and electron density differences. The charge transfer, binding energy, dispersion energy, lattice energy, and energy gap between frontier orbitals in the salts of (**1**) are larger than those of (**2**). This helps stabilize the former, with (**1**) being more stable than (**2**) via the formation of salts. 1,2,4-Triazole is preferred as a base over 1,2,3-triazole in terms of forming stable salts.

Table 21 is a summary of the predicted enthalpies of formation of triazolium salts. The estimates from two different sources, [167] and [374], are included in the table.

**Table 21:** Predicted enthalpies of formation of triazolium salts.

| Compound                                    | Enthalpy of formation |          | References |
|---------------------------------------------|-----------------------|----------|------------|
|                                             | kJ/mol                | kcal/mol |            |
| 5-Azido-1,2,4-triazolium nitrate            | +218.8                | +52.3    | [374]      |
|                                             | +252                  | +60.3    | [167]      |
| 1,2,4-Triazolium 5-nitrotetrazolate         | +409.6                | +97.9    | [374]      |

|                                             | +467                  | +111.6   | [167]      |

### 8.12.2 1,2,4-Triazolium Nitrate and 1,2,3-Triazolium Nitrate

1,2,4-Triazolium nitrate (1,2,4-triazole nitrate) is a high-nitrogen additive and has been repeatedly proposed for gas generant applications. It is soluble in water and is a potential fuel for HAN-based monopropellants.

*In vitro* rat hepatocyte toxicity and bacteria (*Salmonella*) genotoxicity assays were performed on thirteen high-energy chemicals that are candidates for potential

replacement monopropellants for hydrazine [375]. The chemicals were mostly hydrazine derivatives and amino compounds in the form of their nitrate salts. The results in hepatocytes showed a dose-dependent decrease in mitochondrial activity (MTT) and an increase in lactate dehydrogenase (LDH) leakage. 1,2,4-Triazolium nitrate was one of the least toxic compounds tested in this group.

1,2,4-Triazolium nitrate can be prepared by adding concentrated nitric acid dropwise to a solution of 1,2,4-triazole in dry methanol under nitrogen flow at room temperature [201]. In one study, the colorless and homogenous reaction mixture was stirred for 1 h at ambient temperature. After this time, the stirring bar was removed and the solvent was evaporated under a high vacuum to give 1,2,4-triazolium nitrate as white micro-crystals in 93% yield, m.p. 410 K (137 °C) [359, 376, 377].

The thermal decomposition of 1,2,3-triazolium nitrate was studied at four different heating rates [378]. The apparent activation energy and pre-exponential factor of the exothermic decomposition reaction were 134 kJ/mol and  $10^{14.58} \text{ s}^{-1}$ , respectively. The critical temperature of the thermal explosion was 375 K = 102 °C. The entropy ( $\Delta S$ ) and enthalpy ( $\Delta H$ ) of activation and the free energy of activation ( $\Delta G$ ) of the decomposition reaction were 23.88 J mol<sup>-1</sup> K<sup>-1</sup>, 131, and 121 kJ/mol, respectively. The self-accelerating decomposition temperature ( $T_{\text{SADT}}$ ) was 368.6 K = 95.5 °C. The specific heat capacity equation is

$$C_p = -42.6218 + 0.6807T \text{ (for the temperature range } 283.1 < T < 353.2 \text{ K)},$$

where  $C_p$  is the heat capacity in J mol<sup>-1</sup> K<sup>-1</sup> and  $T$  is the temperature in kelvin. The critical temperature of hot-spot initiation was 637 K = 364 °C and the drop height of impact sensitivity (H 50) was 9.16 cm.

The properties of dissolution in different solvents, the specific heat capacity, and the thermal decomposition process under the non-isothermal conditions for energetic triazole ionic salts 1,2,4-triazolium nitrate (**1a**), 1,2,3-triazolium nitrate (**1b**), 3,4,5-triamino-1,2,4-triazolium nitrate (**2a**), and 3,4,5-triamino-1,2,4-triazolium dinitramide (**2b**) were measured using a Calvet Microcalorimeter [379]. The thermochemical equilibrium equation, differential enthalpies of dissolution, standard molar enthalpies of dissolution, apparent activation energy, pre-exponential constant, kinetic equation, linear relationship of specific heat capacity with temperature over the temperature range of 283 to 353 K, standard molar heat capacity and enthalpy, entropy and Gibbs free-energy of 283 to 353 K (taking 298.15 K as the benchmark for compounds **1a**, **1b**, **2a**, and **2b**) were obtained based on experimental data and theoretical calculation methods. In addition, the kinetic and thermodynamic parameters of the thermal decomposition reaction, the critical temperature of thermal explosion, the self-accelerating decomposition temperature, and the adiabatic time-to-explosion of compounds **1a**, **1b**, **2a**, and **2b** were calculated.

An MDs study was performed where several triazolium-based cations (1,2,4-triazolium, 1,2,3-triazolium, 4-amino-1,2,4-triazolium, and 1-methyl-4-amino-1,2,4-triazolium) were paired with nitrate or perchlorate anions [380]. Properties of the more

common ionic liquid, 1-*n*-butyl-3-methylimidazolium nitrate, were also computed and compared with the properties of the triazolium-based compounds. A molecular mechanic force field was developed for these materials using a mix of *ab initio* calculations and parameter fitting, using the molecular compound 1*H*-1,2,4-triazole as a basis for the triazolium cations. Liquid-phase properties that were computed included heat capacities, cohesive energy densities, gravimetric densities/molar volumes as a function of temperature and pressure, self-diffusivities, rotational time constants, and various pair correlation functions. Heat capacities and lattice parameters were computed for the solid phase. Of all of these properties, only lattice parameters have been measured experimentally (and only for four of the triazolium compounds). The agreement with the experimental crystal structures was good. When compared with that of the imidazolium-based ionic liquid, the triazolium-based materials have much smaller molar volumes, higher cohesive energy densities, and larger specific heat capacities. They also tended to be less compressible, have a higher gravimetric density, and have faster rotational dynamics but similar translational dynamics.

### 8.12.3 1,2,4-Triazolium Azides and 1,2,3-Triazolium Azides

Ionic liquid azides from azidoethyl, alkyl, and alkenyl substituted derivatives of 1,2,4- and 1,2,3-amino-triazoles were prepared and their structural and physical properties were determined (Table 22) [163]. All salts possessed melting points below 373K

**Table 22:** Physical properties of di-substituted triazolium azides.

| Compound name                                     | Melting or glass transition point |             | Decomposition onset |      | Calculated $\Delta H_f^{298}(S)$ |          | Impact sensitivity |
|---------------------------------------------------|-----------------------------------|-------------|---------------------|------|----------------------------------|----------|--------------------|
|                                                   | K                                 | °C          | K                   | °C   | kJ/mol                           | kcal/mol | kg cm              |

Data source: [163].

(100 °C). The unique character of these ionic liquid azides is based upon the fact that these molecules are not simple protonated salts like previously reported substituted hydrazinium azides. The presence of quaternary nitrogen seems to confer both thermal stability and reduced volatility.

#### 8.12.4 Other Unsubstituted 1,2,4-Triazolium, 1,2,4-Triazolate, and 1,2,3-Triazolium Salts

Special interest has been devoted to azolium azolate salts such as triazolium nitrotriazolate salts, which sport both a high energy and a high nitrogen content. Energetic salts containing substituted imidazolium and 1,2,4-triazolium cations and 4,5-dinitro-imidazolate and 5-nitrotetrazolate anions were synthesized and characterized [10]. Based on experimentally obtained heats of combustion, the calculated HOFs ranged from  $\Delta H_f^\circ = +80$  to  $+1071$  kJ/mol. Imidazolate salts are denser but have lower HOFs than their tetrazolate analogues. Several salts had melting points  $<100^\circ\text{C}$ . 1,2,4-triazolium perchlorate undergoes a large endothermic crystalline phase change at 362 K (89 °C) and starts to decompose at 548 K (275 °C), as determined by DSC [359, 376, 377]. Triazolium dinitromethanide salts can be very insensitive to impact [381].

#### 8.12.5 Mono-Substituted 1,2,3-Triazolium and 1,2,3-Triazolate Salts

Direct alkylation of 1(H)-1,2,3-triazoles usually forms mixtures of one- and two-substituted 1,2,3-triazoles, which are often difficult to separate. Once formed, they often undergo isomerization equilibria in solution.

1-Amino-1,2,3-triazole, triazol-1-amine, 3-amino-1,2,3-triazole,  $\text{C}_2\text{H}_4\text{N}_4$ , CAS RN [155-25-9], can be synthesized from glyoxal and hydrazine followed by oxidation with manganese(IV)dioxide:

4-Amino-1,2,4-triazolium nitrate melts at 342 K (69 °C) and 4-amino-1,2,4-triazolium perchlorate melts at 357 K (84 °C) [359, 376, 377]. High-density energetic salts that contained the 1-amino-1,2,3-triazole (ATZ) or 3-methyl-1-amino-1,2,3-triazole (MAT) cation and nitrogen-rich anions were synthesized and characterized by IR,  $^1\text{H}$  and  $^{13}\text{C}$  NMR, DSC, and impact sensitivity [382]. 1-Amino-1,2,3-triazolium 5-nitrotetrazolate, 3-methyl-1-amino-1,2,3-triazolium 5-nitrotetrazolate, and 3-methyl-1-amino-1,2,3-triazolium azotetrazolate crystallize in the triclinic space group  $P\bar{1}$ . Their densities were 1.688, 1.588, and  $1.550\text{ g/cm}^3$ , respectively. The measured densities of the other organic energetic salts ranged between 1.56 and  $1.86\text{ g/cm}^3$ . The detonation pressures

calculated for these salts ranged from 21.2 to 37.3 GPa, and the detonation velocities ranged from 7239 to 9082 m/s.

The thermal decomposition kinetics of 1-amino-1,2,3-triazolium nitrate were investigated by non-isothermal TG-DTG at various heating rates (2, 5, 10, 15, and 20 °C/min) [383, 384]. The results showed that the thermal decomposition of 1-amino-1,2,3-triazolium nitrate consisted of two mass-loss stages. At a heating rate of 2 °C/min, two mass-loss stages appeared in the TGA-DTG curve within the ranges 372–434 K (99–161 °C) and 434–460 K (161–187 °C), respectively. The first mass-loss stage corresponded to the loss of nitrate anion and the substituent group, while the second stage corresponded to the splitting of the triazole ring. The apparent activation energies and pre-exponential factors  $\log A$  values for the first decomposition stage were  $E = 128.97$  kJ/mol and  $\log A = 13.78$  s<sup>-1</sup>. Those for the second stage were  $E = 117.37$  kJ/mol and  $\log A = 10.93$  s<sup>-1</sup>, respectively

#### 8.12.6 Di-Substituted 1,2,3-Triazolium and 1,2,3-Triazolate Salts

Quaternization of 1-amino-1,2,3-triazole with alkyl iodide gives quaternary triazolium halogenide salts. However, they have high melting points and do not qualify as ionic liquids [385].

$\text{X} = \text{I}^-$ ,  $\text{R} = \text{CH}_3$ ;  $\text{X} = \text{Br}^-$ ,  $\text{R} = \text{C}_2\text{H}_5$ ,  $\text{C}_3\text{H}_7$ ,  $\text{C}_4\text{H}_9$

Quaternary salts based upon 3-alkyl substituted 1-amino-1,2,3-triazolium cations (alkyl = methyl, ethyl, *n*-propyl, 2-propenyl, and *n*-butyl) have been synthesized and characterized by vibrational spectra, multi-nuclear NMR, elemental analysis, and DSC studies. Subsequent diazotization of these salts resulted in the exclusive formation of 1-alkyl-1,2,3-triazoles. Single-crystal X-ray studies were carried out for 1-amino-3-methyl-1,2,3-triazolium iodide, 1-amino-3-ethyl-1,2,3-triazolium bromide, 1-amino-3-*n*-propyl-1,2,3-triazolium bromide, and 1-amino-3-*n*-butyl-1,2,3-triazolium bromide as well as for the starting heterocycle and 1-amino-1,2,3-triazole itself. The quaternary triazolium halogenides can be reacted with silver nitrate in a metathetical reaction to form the nitrates which are of more interest as rocket propellants [386, 387]. The melting points of five of the nitrate salts are summarized in Table 23. One of the salts with a short alkyl group, 1-amino-3-methyl-1,2,3-triazole nitrate (1-AMTN), was identified as a viable candidate as a TNT replacement due to its relatively high melting point of 361 K (88 °C).

**Table 23:** Melting points of 1-amino-3-alkyl-1,2,3-triazolium nitrates.

| Compound name                             | Gross formula                                                | Molecular mass | Melting Point |    |
|-------------------------------------------|--------------------------------------------------------------|----------------|---------------|----|

Data source: [386].

1-Amino-3-methyl-1,2,3-triazolium nitrate (1-AMTN) was synthesized using glyoxal and hydrazine hydrate as starting materials in three steps, i.e., addition-elimination, cyclization, methylation, and replacement reaction [388]. The overall yield was 71.8% (based on glyoxal). The structure of products was confirmed by IR, MS, NMR, and elemental analysis. The properties of 1-AMTN were estimated as follows: density 1.63 g/cm<sup>3</sup>, enthalpy of formation 84 kJ/mol, and detonation velocity 8115 m/s. Other sources gave the HOF of 1-AMTN as +83.7 kJ/mol (+20 kcal/mol) (estimated) [365]. The onset of decomposition of 1-AMTN in the DSC was at 530 K (257 °C), so it is relatively stable.

Traditionally, the conversion from quaternized alkyl-amino-triazolium halogenides to the desired and more energetic nitrates has been accomplished via a metathetical reaction with silver nitrate, which is expensive. A more economical and cleaner method of conversion, which leads to obtaining a product free of metal salts, is the reaction of triazolium halogenides with dinitrogen tetroxide [389, 390]. Three 1-alkyl-4-amino-1,2,4-triazolium bromides (alkyl = hydroxyethyl, propionitrile, acetonitrile) and 1-amino-3-propyl-1,2,3-triazolium bromide were chosen as typical examples of the process.

MD simulations based on both electronically non-polarizable and polarizable models have been carried out to investigate the ionic liquid 1-hydroxyethyl-4-amino-1,2,4-triazolium nitrate [391]. The intention was to not only provide simulation data but also to provide insight into the relationship between molecular structure, dynamics, and other useful physical properties for this class of ionic liquids. Replacing the ethyl group in 1-ethyl-4-methyl-1,4-imidazolium nitrate by a 2-hydroxyethyl group created an ionic liquid with an interwoven network of hydrogen bonds. This was simulated by MD calculations and the predicted glass transition temperature closely matched that measured by experiments.

The 1,3-diamino-1,2,3-triazolium cation can be prepared by the amination of 1-amino-1,2,3-triazole with *O*-tosylhydroxylamine [392]. The cation was then paired with the energetic anions nitrate, nitrotetrazolate-2-oxide, 5,5'-bis(1-oxidotetrazolate), 5,5'-azobis(1-oxidotetrazolate), and nitriminotetrazolate. The resulting salts were

characterized. The HOFs and detonation properties were calculated and the impact, friction, and electrical spark sensitivities of the 1,3-diamino-1,2,3-triazolium salts were measured. These salts were easily initiated energetic materials.

The energetic ionic liquid 4-amino-1-butyl-1,2,4-triazolium nitrate (C4N) can be prepared via a one-step metal-free route using butyl nitrate [393]. C4N offers promising properties like very low vapor pressure combined with good insensitivity. The potential use as an energetic additive to improve the rheological properties of glycidyl azide polymer-based (GAP-based) energetic polymers has been studied, resulting in an almost four times lower viscosity at 15 mass-% C4N content. As an additive to a nitromethane-based monopropellant, C4N works as a burning rate modifier. This reduces the propellant sensitivity.

### 8.12.7 Mono-Substituted 1,2,4-Triazolium and 1,2,4-Triazolate Salts

#### 4-Amino-1,2,4-triazolium and 1,2,4-Triazolate Salts

4-Amino-1,2,4-triazole forms stable salts with most mineral acids and nitroform. It also forms quaternary salts with methyl iodide [328].

#### 4-Amino-1,2,4-triazolium Salts

4-Amino-1,2,4-triazolium nitrate (4-amino-1,2,4-triazole nitrate) is a high-nitrogen additive and has been repeatedly proposed for use in gas generant applications. It is also soluble in water and is a potential fuel for HAN-based monopropellants.

4-Amino-1,2,4-triazolium nitrate can be prepared by adding concentrated nitric acid dropwise to a solution of 4-amino-1,2,4-triazole in dry methanol under nitrogen flow at room temperature [201]. The colorless and homogeneous reaction mixture was stirred for 1 h at ambient temperature. After 1 h, the stirring bar was removed and the solvent was evaporated under a high vacuum. This produced 4-amino-1,2,4-triazolium nitrate as colorless crystal prisms in 89% yield, m.p. 342 K (69 °C).

*In vitro* rat hepatocyte toxicity and bacteria (*Salmonella*) genotoxicity assays were performed on 13 high-energy chemicals that are candidates for potential replacement monopropellants for hydrazine [375]. The chemicals were mostly hydrazine derivatives and amino compounds in the form of their nitrate salts. The results in hepatocytes revealed a dose-dependent decrease in MTT and an increase in LDH leakage. 4-Amino-1,2,4-triazolium nitrate was one of the least toxic compounds tested in this group.

The amino group can be attached to either the 3-position or in the 4-position in 1,2,4-triazole or in the 1-position in 1,2,3-triazole.

4-Amino-1,2,4-triazole

1-Amino-1,2,3-triazole

The 4-amino-1,2,4-triazole is the more commonly synthesized compound. However, the oxidizing anion salts of 3-alkyl-substituted 1-amino-1,2,3-triazoles have also been investigated [362]. The melting points of several 4-amino-1,2,4-triazolium salts are summarized in Table 18. 1,2,3-Triazole derivatives generally have higher melting points and glass transition temperatures than the corresponding 1,2,4-triazole isomers. Properties of amino-1,2,4-triazolium salts are summarized in Table 24.

**Table 24:** Properties of aminotriazolium salts.

| Compound                                              | $T_{\text{melt}}(T_{\text{glass}})$ |     | $T_{\text{dec}}$ |     | Density, meas.    | Density, calc. from XRD |

Data source: [309].

The initiation of the decomposition of several EILs, including 4-amino-1,2,4-triazolium nitrate, was studied using confined rapid thermolysis (CRT). Rapid-scan FTIR spectroscopy and TOF mass spectrometry were utilized to identify the products evolved from sub-milligram quantities that were subjected to heating rates of about 2000 K/s [394]. 4-amino-1,2,4-triazolium nitrate is a crystalline white solid under standard conditions. 4-amino-1,2,4-triazolium nitrate was found to undergo thermolysis through a proton transfer involving (primarily) the amino group to form HNO<sub>3</sub>. Subsequent reactions led to the formation of 1*H*-1,2,4-triazole. The highly energetic nitrate salt formed copious amounts of H<sub>2</sub>O and N<sub>2</sub>O through multiple secondary reaction channels.

The thermal decomposition of two EILs, formed by pairing the 4-amino-1,2,4-triazolium cation with chloride (4ATCl), and nitrate (4ATN) anions, was studied by CRT [395]. A combination of rapid-scan FTIR spectroscopy and TOF mass spectrometry was used to identify the products of decomposition at heating rates of 2000 K/s and temperatures of up to 340 °C in an ambient inert gas at 1 atm. Whereas a proton transfer

from the N1 position primarily initiated decomposition in 4ATCl, the amino group was found to primarily participate in the initiation reaction in the case of 4ATN. The parent molecule, 1*H*-1,2,4-triazole, was detected during subsequent reactions. Ring fracture was also evident from the presence of HCN. The highly energetic nitrate salt formed copious amounts of H<sub>2</sub>O and N<sub>2</sub>O through multiple secondary reaction channels.

The behavior of an ionic liquid, 1*H*-4-amino-1,2,4-triazolium nitrate, during thermal decomposition driven by an IR laser (10.6  $\mu\text{m}$ ) with a laser heat flux of 100 W/cm<sup>2</sup> in helium at 1 atm was examined in comparison to three other materials: 4-amino-1,2,4-triazolium hydrochloride, 4-amino-1,2,4-triazole, and 1*H*-1,2,4-triazole [396]. The focus was to understand the initial decomposition reaction steps and subsequent reactions that lead to ring decomposition and, eventually, to ignition. A triple quadrupole mass spectrometer with molecular beam sampling was used to obtain gaseous decomposition products of the sample. The results showed that the most probable route to initiate the decomposition of the 1*H*-4-amino-1,2,4-triazolium nitrate is through proton transfer from an N1 site to the nitrate, thus forming a neutral pair of nitric acid and amino-triazole. Subsequent reactions involve the decomposition of the neutral pair and their interactions.

Energetic nitroformate salts that contain high-nitrogen cations were synthesized and characterized by elemental, spectral, and thermal analyses [397]. Single-crystal XRD of 4-amino-1,2,4-triazolium nitroformate revealed that it is a co-crystal of a neutral 4-amino-1,2,4-triazole molecule with the 4-amino-1,2,4-triazolium nitroformate ion pair. The presence of the neutral molecule appears to lend stability to the salt. The structure of 3,6-diguanidino-1,2,4,5-tetrazinium nitroformate was confirmed by single-crystal XRD. Theoretical performance calculations indicated that these materials have properties that compare favorably with hydrazinium nitroformate, TNT, and tetryl, suggesting potential applications as eco-friendly oxidizers.

The rates of decomposition of 4-amino-1,2,4-triazolium nitrate (4ATN) were measured by CRT. Arrhenius-type reaction rate parameters for the initiation reactions governing the thermal decomposition were determined by numerical techniques [398]. The reaction rate parameters were obtained by an algorithm that compared the difference between the experimental and simulated species evolution profiles from the decomposition process. The decomposition process was simulated by applying conservation and equilibrium equations to the condensed and gas phases individually. The processes governing the decomposition of these energetic compounds were found to be autocatalytic in nature. The autocatalytic agents were the strong acids generated by the initial decomposition step. The activation energy  $E_{\text{act}}$  and pre-exponential factor  $A$  for the unimolecular decomposition step for 4ATN was 167 kJ/mol and 10<sup>16</sup> s<sup>-1</sup>, respectively. This is similar to previously determined values for AN.

An ionic compound (3-ATz)<sup>+</sup> (NTO)<sup>-</sup> was synthesized by the reaction of 3-amino-1,2,4-triazole (3-ATz) with 3-nitro-1,2,4-triazol-5-one (NTO) in ethanol [399]. Single crystals suitable for XRD were obtained by crystallization at room temperature. The crystal is monoclinic, space group  $P2_1/c$  with crystal parameters of  $a = 0.6519(2)$  nm,

$b = 1.9075(7)$  nm,  $c = 0.6766(2)$  nm, and  $\beta = 94.236(4)^\circ$ . The self-accelerating thermal decomposition temperature was 505 K and the critical temperature of thermal explosion was 525 K.

3-Amino-1,2,4-triazolium dinitramide was synthesized through the combination of 3-amino-1,2,4-triazole cation and oxygen-rich dinitramide anion. Its structure was confirmed by single-crystal XRD, elemental analysis, FTIR, UV-Vis spectrometry, and NMR [400]. The thermal stability was studied using DSC, TGA, and TGA tandem IR. Results indicated that this salt was thermally stable up to 439 K. The activation energy of the decomposition reaction was  $E_a = 281.9$  kJ/mol. The structure of a salt prepared via a neutralization reaction using 4-amino-1,2,4-triazol and dinitroguanidine as raw materials was characterized by IR and thermodynamic parameters (specific heat capacity, enthalpy, and entropy of formation). The relation between these parameters and the temperature of the energetic ionic salt was calculated using a DFT method [401]. The theoretical density, enthalpy of formation, detonation velocity, and detonation pressure of the ionic salt were estimated using a Monte-Carlo method, Born-Haber cycle, and K-J formulae, respectively. The results showed that the theoretical density, enthalpy of formation, detonation velocity, and detonation pressure of the ionic salt were  $1.72$  g/cm<sup>3</sup>,  $+313.92$  kJ/mol,  $8.15$  km/s, and  $28.53$  GPa, respectively.

The critical temperature of the thermal explosion of the dinitroguanidinium 4-amino-1,2,4-triazolate salt is  $459$  K =  $186^\circ\text{C}$  [402]. The entropy of activation, enthalpy of activation, and free energy of activation of the decomposition reaction are  $\Delta S = 60.22$  J mol<sup>-1</sup> K<sup>-1</sup>,  $\Delta H = 143.24$  kJ/mol, and  $\Delta G = 116.34$  kJ/mol, respectively. The predicted detonation pressure is  $P_{\text{CJ}} = 29.78$  GPa and detonation velocity is  $V_{\text{det}} = 8.28$  km/s. The material was not very sensitive, with the impact sensitivity being  $h_{50} = 135$  cm.

Dinitroguanidinium 4-amino-1,2,4-triazolate

3-Azido-1,2,4-triazolium 5,5'-azotetrazolate is a very sensitive explosive [403]. This salt was characterized by NMR, IR, XRD, and DSC. The sensitivity to mechanical stimuli was also determined by small-scale sensitivity testing, small-scale shock reactivity testing, and small-scale internal blast testing.

### 8.12.8 Di-Substituted 1,2,4-Triazolium and 1,2,4-Triazolate Salts

In this heading, “di-substituted” refers to the sum of functional and alkyl groups.

#### Diamino-1,2,4-triazolium Salts

1,5-Diamino-1,2,4-triazolium nitrate and perchlorate are stable salts prepared directly from the amine and the acid in aqueous solutions [404]. Several energetic salts were synthesized via the quaternization of azido or nitro derivatives of imidazole, 1,2,4-triazole, and substituted derivatives of tetrazole with nitric or perchloric acid or with iodomethane followed by metathesis reaction with silver nitrate or silver perchlorate [328]. The structures of 1,4-dimethyl-3-azido-1,2,4-triazolium nitrate, 3-azido-1,2,4-triazolium nitrate, 1-methyl-4-amino-1,2,4-triazolium perchlorate, and 1,4-dimethyl-2-*H*-1,2,4-triazolium triiodide were confirmed by single-crystal XRD. Most of the salts exhibited good thermal stabilities and low melting points. By using constant volume combustion energies that were determined experimentally using an oxygen bomb calorimeter, the standard molar enthalpies of formation were derived based on designed Hess thermochemical cycles.

EILs based on anionic lanthanide nitrate complexes  $\text{Cat}^{+3}[\text{Ln}(\text{NO}_3)_6]^{3-}$ , where  $\text{Cat}^+$  is guanidinium, 4-aminotriazolium, 4-amino-1-methyltriazolium, 4-amino-1-ethyltriazolium, 4-amino-1-butyltriazolium, 1,5-diaminotetrazolium, and 1,5-diamino-4-methyltetrazolium were prepared and characterized [405]. The hexanitratolanthanate (-cerate) salts with the last two cations, which are the first CO-balanced EILs that are stable to hydrolysis and air, have impact sensitivities of about 27 J. These ionic liquids were obtained by an environmentally friendly and simple method using nitrate-containing precursors. All salts were fully characterized by IR and NMR spectroscopy, elemental analysis, and through the determination of thermal stability, phase behavior, density, and water content. Theoretical thermodynamic equilibrium calculations showed that these new compounds have potential as rocket propellants.

1,5-Diamino-1,2,4-triazolium nitrate and perchlorate and 3,5-diamino-1,2,4-triazolium nitrate and perchlorate are isomers with very similar properties. 3,5-Diamino-1,2,4-triazole was protonated with diluted hydrochloric acid and nitric acid as well as perchloric acid, forming 3,5-diamino-1,2,4-triazolium chloride hemihydrate, 3,5-diamino-1,2,4-triazolium nitrate, and 3,5-diamino-1,2,4-triazolium perchlorate, respectively [406]. As a second reaction step 3,5-diamino-1,2,4-triazolium perchlorate can be made to react with potassium dinitramide, forming 3,5-diamino-1,2,4-triazolium dinitramide and low solubility potassium perchlorate. These compounds were characterized by low-temperature single-crystal XRD, IR, and Raman spectroscopy, as well as multi-nuclear NMR spectroscopy, mass spectrometry, and DSC. The HOFs were calculated by the CBS-4M method, as summarized in Table 25.

**Table 25:** Properties of 3,5-diamino-1,2,4-triazolium salts.

| Compound                                          | Enthalpy of formation, kJ/mol |
|---------------------------------------------------|-------------------------------|
| 3,5-Diamino-1,2,4-triazole                        | +81.1                         |
| 3,5-Diamino-1,2,4-triazolium chloride hemihydrate | +124.7                        |
| 3,5-Diamino-1,2,4-triazolium nitrate              | −76.1                         |
| 3,5-Diamino-1,2,4-triazolium perchlorate          | −25.2                         |
| 3,5-Diamino-1,2,4-triazolium dinitramide          | +138.7                        |

Data source: [406].

With these values and the X-ray densities too, several detonation parameters were calculated using the computer codes EXPLO5.03 and EXPLO5.04. In addition to this, the sensitivities of all compounds were determined by a BAM drop-hammer and a friction tester, as well as a small-scale ESD sensitivity test device.

Energetic salts of 3,4-diamino-triazole such as nitrate and picrate were characterized by FTIR, elemental analysis, DSC, and XRD [407]. Predicted detonation properties were 21.5–32.8 GPa and 7017–8620 m/s, which were much higher than those of TNT.

Several energetic mono- and dicationic 3,4-diaminotriazolium salts were prepared by combining stoichiometric amounts (1:1 or 2:1 molar ratio) of 3,4-diaminotriazole with various oxygen-containing tetrazolates and the structures were confirmed by single-crystal XRD [408]. All structures are dominated by a strong hydrogen-bond network owing to both the amino groups and the oxygen in the molecule. Most salts exhibited excellent thermal stabilities, with decomposition temperatures above 473 K (200 °C) and predicted detonation pressures (20.3–33.9 GPa) and velocities (7095–8642 m/s) above those of conventional explosives.

#### 4-Amino-1-methyl-1,2,4-triazolium Salts

The synthesis methods and some properties of 4-amino-1-methyl-1,2,4-triazolium nitrate (AMTN) were described in [266, 267, 409]. AMTN has a glass transition point of 218 K (−55 °C) and shows good thermal stability. The synthesis of 4-amino-1-methyl-1,2,4-triazolium nitrate via alkylation of 4-amino-1,2,4-triazole with iodomethane and subsequent anion metathesis with silver nitrate lead to an ionic liquid that had a glass transition point of 218 K (−55 °C) and showed low sensitivity against impact (15 Nm) and friction (160 N). Burning tests performed on 4-amino-1-methyl-1,2,4-triazolium nitrate have led to a flame temperature of 2200 K [409]. Combustion experiments of 4-amino-1-methyl-1,2,4-triazolium nitrate and one equimolar liquid mixture of 4-amino-1-methyl-1,2,4-triazole and 4-amino-1-methyl-1,2,4-triazolium nitrate were performed in a pressurized window bomb at room temperature and pressure up to 13 MPa. The samples all showed low-pressure dependence and even slightly decreasing burn rates at higher pressures.

The synthesis of EILs on the base of 4-amino-1,2,4-triazole with nitrate as an anion where the substituents at N1 were methyl, cyanomethyl, and cyanoethyl, resulted in 4-amino-1-methyl-1,2,4-triazolium nitrate, 4-amino-1-(cyanomethyl)-1,2,4-triazolium nitrate and 4-amino-1-(cyanoethyl)-1,2,4-triazolium nitrate. 4-Amino-1-methyl-1,2,4-triazolium nitrate is a room temperature EIL but 4-amino-1-(cyanomethyl)-1,2,4-triazolium nitrate and 4-amino-1-(cyanoethyl)-1,2,4-triazolium nitrate are solids at room temperature [410].

Values for the published enthalpy of formation of AMTN vary substantially. However, none of the three different values can be viewed as reliable until the numbers have been confirmed experimentally:  $-187$  kJ/mol [404],  $+58$  kJ/mol [202], and a theoretical value of  $-27.6$  kJ/mol [167].

4-Amino-1,2,4-triazolium perchlorate (4-ATP), 1-methyl-4-amino-1,2,4-triazolium perchlorate (MATP), and 1-amino-3-methyl-1,2,3-triazolium nitrate (1-AMTN) were evaluated as candidates to replace TNT [411].

### Other Di-Substituted 1,2,4-Triazolium Salts

Heterocyclic rings (containing amino, nitro, or azido substituents) were paired with nitrate, perchlorate, dinitramidate, or picrate anions to form highly energetic salts, which may be more environmentally acceptable as propellants and explosives (perchlorate excepted) [202]. Additionally, high-energy salts in which both the cation and anion are high-nitrogen species, e.g., azolium, substituted azolium, guanidinium, bridged imidazolium, triazolium, and urotropinium cations, etc. coupled with azolates, substituted azolates, azotetrazolate, bis(5,5'-tetrazolates), and iminobis(5-tetrazolate) were synthesized. All have been thoroughly characterized via NMR and mass spectral analyses, melting point, thermal stability, density, and elemental analyses. Computational chemistry methods gave theoretical HOFs and detonation pressure/velocity and specific impulse. In addition to this, an accurate empirical method for the estimation of crystal densities of energetic compounds was developed. Substituted imidazolium, triazolium, and tetrazolium cations were combined with nitrodicyanomethanide and dinitrocyanomethanide anions to produce a new class of ionic liquids. 1,2,4-Triazolium cations with  $-\text{CH}_3$ ,  $-\text{NH}_2$ , or  $-\text{N}_3$  substituents on the rings were combined with 4,5-dinitroimidazolate or 5-nitrotetrazolate anions to form a wide array of salts and a few ionic liquids. Table 26 is a summary of the properties of these energetic compounds.

Amino- and/or methyl-substituted imidazolium, triazolium, and tetrazolium cations were combined with nitrodicyanomethanide and dinitrocyanomethanide anions to

**Table 26:** Properties of 1,2,4-triazolium 4,5-dinitroimidazoles or 5-nitrotetrazolates.

Data source: [202]

produce a new class of ionic liquids [202, 412, 413]. Phase transition temperatures (mid-points of glass transition and/or melting points) were determined by DSC and compared to data for the corresponding, well-known nitrate salts (Table 27). That table also contains measured and calculated density and enthalpies of formation. The nitrodiacyanomethanide anion has a positive calculated HOF (32.2 kJ/mol), which is higher than that of dinitrocyanomethanide (−127.7 kJ/mol) and much higher than that of nitrate (−307.9 kJ/mol). With a constant anion, the effect of cation on density is in the order of 1,5-diamino-4-methyltetrazolium > 1,4-dimethyl-5-aminotetrazolium > 1,4,5-trimethyltetrazolium > 1,4-dimethyltriazolium > 1,3-dimethylimidazolium. The melting points of dinitrocyanomethanide salts were higher than those of nitrodiacyanomethanide analogues (see also [414]).

AMTN is an EIL, fitting the practical demands with a glass transition point of 218 K (−55 °C) and with good thermal stability of above 473 K (200 °C). Because of the asymmetrical triazolium cation and the symmetrical nitrate anion, efficient crystal packing is inhibited. The physical properties of four substituted triazolium salts are summarized in Table 28.

The combustion behavior of these EILs was investigated in a windowed bomb under pressures up to 15 MPa. This resulted in a linear burning characteristic with low-pressure dependence. Samples were transferred into glass test tubes (Ø 8 mm) and burnt by a method similar to the one used for solid propellant strands in a windowed

**Table 27:** Properties of nitrodicyanomethanide and dinitrocyanoamethanide salts.

bomb under nitrogen at pressures up to 15 MPa at room temperature. Soon after ignition, using a melting wire, stable combustion developed with a distinct and intensively emitting reaction inside the condensed phase. Pure AMTN burned only at pressures above 13 MPa. The pressure dependence of AMTN and some of its mixtures with fuels was linear but very flat (low-pressure coefficient).

In addition to this, 4-amino-1-methyl-1,2,4-triazolium perchlorate (AMTP) was synthesized and characterized. With its melting point close to that of TNT, AMTP has potential as a melt cast explosive. For comparison, the 4-amino-1-*H*-1,2,4-triazolium

salts were also synthesized (AHTP = 4-amino-1-*H*-1,2,4-triazolium perchlorate, AHTN = 4-amino-1-*H*-1,2,4-triazolium nitrate). AHTP is very sensitive to friction and impact and must be handled with extreme caution.

The thermal decomposition of the EILs 1-methyl-4-amino-1,2,4-triazolium iodide, 1-methyl-4-amino-1,2,4-triazolium nitrate, 1-amino-3-methyl-1,2,3-triazolium iodide, and 1-amino-3-methyl-1,2,3-triazolium nitrate was studied by CRT at rates of approximately 2000 K/s [415]. The products formed by decomposition were analyzed by rapid-scan FTIR spectroscopy and TOF mass spectrometry. Decomposition studies involving the nitrate salts were conducted at 593–613 K (320–340 °C). The amino group was found to be involved in the initiation reaction, forming copious quantities of ammonia from the iodide compounds and N<sub>2</sub>O and H<sub>2</sub>O from the nitrate compounds. The extent of decomposition of the triazole ring was minimal at the considered temperatures. The melting points of 3-alkyl-1-amino-1,2,3-triazolium perchlorates with different length alkyl chains are summarized in Table 29.

The initial quaternization of 4-amino-1,2,4-triazole is often performed with an alkyl bromide, leading to the 1-alkyl-4-amino-1,2,4-triazolium bromide. Crystalline 1-ethyl-4-amino-1,2,4-triazolium bromide has extensive hydrogen bonding [376]. The bromides are only intermediates awaiting substitution of the bromide with more energetic oxidizing anions. The metathetical reaction, which exchanges the anions, is often done with the silver salts of the oxidizing anion, e.g., silver nitrate or silver perchlorate. This causes less soluble silver bromide to precipitate. The properties of 1-alkyl-4-amino-1,2,4-triazolium nitrates with different length alkyl chains are summarized in Table 30. Data is available for long alkyl chains up to C<sub>10</sub> but are not included here [377]. The melting point goes through a minimum at C<sub>4</sub>.

Data source: [359, 376, 377, 416].

A DSC thermogram of a typical ionic liquid (1-*n*-propyl-4-amino-1,2,4-triazolium nitrate) is shown in Figure 8 as an example. The event at 255 K (−18 °C) is a phase transition point.

The corresponding perchlorates are thermally more stable than the nitrates (see Table 31). Similar data are available for the triazolium nitrocyanamidate salts. The dinitramide salt is very friction sensitive and does not tend to crystallize but remains in the form of a yellow oil [359].

Ionic liquids based upon the halide and nitrate salts of 1-alkyl substituted-4-amino-1,2,4-triazolium cations (*n*-alkyl = methyl, decyl, isopropyl, allyl, and methylcyclopropyl) have been synthesized and characterized by vibrational spectra, multi-nuclear NMR, elemental analysis, and DSC [417]. Single-crystal XRD identified the crystal structures of 1-isopropyl-4-amino-1,2,4-triazolium nitrate, 1-methylcyclopropyl-4-amino-1,2,4-triazolium nitrate, and several halides. It also pointed out similarities, differences, and the effects of strong hydrogen bonding in all of the structures.

4-Amino-1-(cyanomethyl)-1,2,4-triazolium dinitramide was synthesized by quaternization of 4-amino-1,2,4-triazole with chloroacetonitrile and subsequent anion metathesis [418]. The product was characterized by <sup>1</sup>H-NMR, <sup>13</sup>C-NMR, FTIR,

Data source: [359,376].

Raman spectra, DSC, TGA, density, and impact and friction sensitivity tests. The enthalpy of formation was calculated from the heat of combustion. With a m.p. of 343 K (+70 °C) and a glass transition point of 236 K (-37 °C), this dinitramide salt can be classified as an energetic ionic liquid.

4-Amino-1-methyl-1,2,4-triazolium dicyanamidate was used as an ionic liquid to suspend ball-milled nano-boron particles, creating fuel with a very high heat of combustion that is suitable for air-breathing engines [419]. The ionic liquid not only suspends the particles during ball-milling but also protects the freshly formed

surface from oxidation which would otherwise detract from the heat of combustion of the slurry. A typical slurry would contain 10 mass-% boron. It can also be used as a bipropellant fuel with NTO or RFNA as the oxidizer.

The structure of two different EILs and the nature of their binding to elemental boron surfaces were investigated by a combination of X-ray photoelectron spectroscopy (XPS), IR spectroscopy, zeta potential measurements, TGA, and calculations based on first-principles theory [420]. It was found that both 1-methyl-4-amino-1,2,4-triazolium dicyanamidate and 1-butyl-3-methylimidazolium dicyanamidate ionic liquids bind to boron well enough to resist removal by ultrasonic washing and to protect the boron surface from oxidation during air exposure of the washed powder. The data suggested that both the cation and the anion of the ionic liquids interact with the boron surface.

The structure of hydrazinium 3,5-dinitroamino-1,2,4-triazolate (HDNAT) was investigated with IR, MS,  $^{13}\text{C}$ -NMR, SEM, and XRD [421]. The X-ray crystal density of HDNAT was  $1.91\text{ g/cm}^3$ . The crystal belongs to a monoclinic system with the space group  $P2_1$ . The thermal decomposition of HDNAT was investigated by TG-DTA at a heating rate of  $10\text{ K/min}$  and by using DSC under non-isothermal conditions. The decomposition kinetic and thermodynamic parameters were obtained by the Kissinger and Ozawa method. HDNAT can be analyzed via HPLC with water/ acetonitrile/trifluoroacetic acid (97/3/0.1 by volume) as the mobile phase.

#### **Nitro-1,2,4-triazolate Salts and Azido-nitro-1,2,4-triazolate Salts**

5-Azido-3-nitro-1*H*-1,2,4-triazole can be prepared using commercially available raw chemicals in a three-step synthesis. From the free acid, several metal and nitrogen-rich salts with sodium, potassium, cesium, silver, lead, ammonium, guanidinium, and aminoguanidinium were prepared via simple acid-base reactions [422]. All compounds were characterized by IR, Raman, NMR, MS, and DSC. The sensitivities towards external stimuli (impact, friction, electrostatic discharge) were determined according to BAM standards. The metal salts are very sensitive and were tested as potential primary explosives.

#### **8.12.9 Di-Substituted 1,2,3-Triazole Salts**

The synthesis and structural characterization of ammonium, guanidinium, aminoguanidinium, diaminoguanidinium, and triaminoguanidinium 4,5-dicyano-1,2,3-triazolate salts provided information on a new group of high-nitrogen compounds [423]. The neutral parent compound 4,5-dicyano-2*H*-triazole was also prepared and spectroscopically characterized using  $^1\text{H}$ ,  $^{13}\text{C}$ , and  $^{15}\text{N}$  NMR, IR, and Raman spectroscopy, as well as DSC and mass spectrometry. The impact and friction sensitivities of the salts were investigated using drop-hammer and friction apparatus methods. All compounds were found to be neither impact ( $>30\text{ J}$ ) nor friction sensitive ( $>360\text{ N}$ ). The crystal structures are summarized in Table 32.

Table 32: Crystal structures of 4,5-dicyano-2*H*-triazole and 4,5-dicyano-2*H*-triazolate salts.

Data source: [423].

4,5-Dicyano-2*H*-1,2,3-triazole forms a 4,5-dicyano-2*H*-1,2,3-triazolate anion  $[\text{C}_4\text{N}_5]^-$  that can form salts with organic nitrogen-containing bases such as the ones listed in Table 31 or with metals [424].

### 8.12.10 Tri-Substituted 1,2,4-Triazolium and 1,2,4-Triazolate Salts

#### 3,4,5-Triamino-1,2,4-triazolium Salts

The parent amine of this group of salts, 3,4,5-triamino-1,2,4-triazole (“guanazine”) is relatively easily obtained by synthesis starting with hydrazine and dimethylcyanamide. It has a relatively high melting point of 527 K (254 °C) and has poor solubility in polar solvents. The enthalpy of formation of the parent amine was estimated to be +234.3 kJ/mol (+56 kcal/mol). The salts are well crystallized. The melting points of the nitrate, perchlorate, and dinitramide salts have already been detailed in Table 18.

Reactions of 3,4,5-triamino-1,2,4-triazole (guanazine) with strong acids ( $\text{HNO}_3$ ,  $\text{HClO}_4$ , and  $\text{HN}(\text{NO}_2)_2$ ) resulted in a family of highly stable salts [425, 426]. All of the salts were characterized using spectroscopic as well as single-crystal XRD techniques. The X-ray structures were compared to those obtained from theoretical calculations. Initial safety testing (impact, friction) was also carried out on all of the new materials. Properties of 3,4,5-triamino-1,2,4-triazolium salts are listed in Table 33.

3,4,5-Triamino-1,2,4-triazolium 5-nitrotetrazolate can be synthesized in high yield from 3,4,5-triamino-1,2,4-triazole (guanazine) and ammonium 5-nitrotetrazolate [427]. The compound was characterized by vibrational (IR and Raman) and multi-nuclear NMR spectroscopy, elemental analysis, and single-crystal XRD. The crystal structure was triclinic, space group  $P\bar{1}$ ,  $a = 0.7194(5)$  nm,  $b = 0.8215(5)$  nm,  $c = 0.8668(5)$  nm,  $\alpha = 75.307(5)^\circ$ ,  $\beta = 70.054(5)^\circ$ ,  $\gamma = 68.104(5)^\circ$ ,  $V = 0.4421(5)$  nm<sup>3</sup>,  $Z = 2$ ,  $\rho = 1.722$  g/cm<sup>3</sup>. The <sup>15</sup>N NMR spectrum and X-ray crystal structure of 3,4,5-triamino-1,2,4-triazole (guanazine) was triclinic, space group  $P\bar{1}$ ,  $a = 0.5578(5)$  nm,  $b = 0.6166(5)$  nm,  $c = 0.7395(5)$  nm,  $\alpha = 114.485(5)^\circ$ ,  $\beta = 90.810(5)^\circ$ ,  $\gamma = 97.846(5)^\circ$ ,  $V = 0.2286(3)$  nm<sup>3</sup>,  $Z = 2$ , and  $\rho = 1.658$  g/cm<sup>3</sup>.

A series of new energetic salts based on the polyamino-1-guanyl-1,2,4-triazolium cation with three to five amino groups and the dinitramide anion were synthesized [428]. These new nitrogen-rich salts tended to have extensive hydrogen bonding and exhibited high densities and good thermal stabilities. Their properties were modified by varying the guanyl substituents and/or the amino substituents on the triazole ring. Based on theoretical calculations, 3,5-diamino-1-guanyl-1,2,4-triazole dinitramide, (density 1.78 g/mL, onset of exotherm 470 K = 197 °C, det. vel. 8775 m/s) had a higher detonation pressure and higher velocity values than other dinitramide energetic materials such as ADN or *N*-guanylurea-dinitramide (FOX-12). The structures of 3-amino-1-guanyl-1,2,4-triazole dinitramide, 3,5-diamino-1-guanyl-1,2,4-triazole dinitramide, 5-amino-*N*-amidino-1-guanyl-1,2,4-triazole dinitramide, and

3,5-diamino-*N*-amidino-1-guanyl-1,2,4-triazole dinitramide were investigated using single-crystal XRD.

Thermally stable energetic salts were synthesized from 3,4,5-triamino-1,2,4-triazole, including the picrate and azotetrazolate salts [429]. 3,4,5-Triamino-1,2,4-triazolium picrate and bis(3,4,5-triamino-1,2,4-triazolium) 5,5'-azotetrazolate were characterized analytically, spectroscopically, and by XRD. The standard enthalpy of formation from calculations was predicted to be  $\Delta H_f^\circ = -498.3 \text{ kJ/mol}$  for the picrate and  $\Delta H_f^\circ = +524.2 \text{ kJ/mol}$  for the azotetrazolate. Predicted detonation velocities were 7015 and 7683 m/s, respectively.

The dinitramide salt of 3,4,5-triamino-1,2,4-triazole can be prepared via the addition of concentrated HCl to 3,4,5-triamino-1,2,4-triazole in deionized water followed by the addition of hydrogen dinitramide and purification [430]. It can be dissolved in and recrystallized from *N*-methyl pyrrolidone. The heat of solution was determined in a calorimeter [431].

Highly dense nitrogen-rich ionic compounds are potential high-performance energetic materials for use in military and industrial venues. 3,4,5-triamino-1,2,4-triazolium (guanazinium) salts with promising energetic anions and a family of energetic salts based on nitrogen-rich cations and the 6-nitroamino-2,4-diazido-[1,3,5]triazinate anion (NADAT) were prepared and fully characterized by elemental analysis, IR,  $^1\text{H}$  NMR and  $^{13}\text{C}$  NMR, and DSC [432]. The crystal structures of neutral NADAT and its biguanidinium salt were determined by single-crystal XRD. All the new salts exhibited desirable physical properties such as relatively high densities ( $1.63\text{--}1.78 \text{ g/cm}^3$ ) and moderate thermal stabilities ( $T_{\text{dec}} = 403\text{--}469 \text{ K} = 130\text{--}196^\circ\text{C}$ ) for 3,4,5-triamino-1,2,4-triazolium salts and ( $T_{\text{dec}} = 482\text{--}530 \text{ K} = 209\text{--}257^\circ\text{C}$ ) for 6-nitroamino-2,4-diazido[1,3,5]triazinate salts. Theoretical performance calculations gave detonation pressures and velocities in the range of 21.0–30.3 GPa and 7675–9048 m/s, respectively, which makes them competitive energetic materials.

#### 8.12.11 Tetra-Substituted 1,2,4-Triazolium Salts

Tetra-substitution, as in 1-alkyl-3-perfluoroalkyl-4,5-dimethyl-1,2,4-triazolium salts, was difficult to obtain [433]. Of the 19 triazolium salts synthesized and characterized, seven were liquids at 298 K (25°C). These were all nitrates and all had negative  $\Delta H_f^\circ$ 's [202]. Only four of the perchlorates had melting points of  $<373 \text{ K}$  ( $<100^\circ\text{C}$ ).

### 8.13 1,2,4-Triazol-5-one and Triazolone Derivatives

Triazolone, 1,4-dihydro-1,2,4-triazol-5-one,  $C_2H_3N_3O$ , CAS RN [930-33-6], differs from triazole in that the  $>CH_2$  group has been replaced by a keto  $>C=O$  group.

Triazolone-5

The parent molecule of several high-energy materials and unsubstituted triazolone-5 can be made from semicarbazide and formic acid or formic acid ester [434]. 1,2,4-triazol-5-one (TO) can be made by heating a mixture of hydrazodicarbonamide and formic acid to a reflux temperature, thus refluxing and removing unreacted formic acid [435]. TO serves as the starting product for NTO.

Triazolone-5 was investigated to better understand the thermal stability of some of its even more energetic derivatives. The structures of two isomers of 1,2,4-triazol-5-one (1,2,4-trihydro-1,2,4-triazol-5-one and 2,3,4-trihydro-1,2,4-triazol-5-one) were fully optimized by DFT computational methods [436]. The geometry, electron structure, net charges of atoms, and vibration spectroscopic properties were calculated. The stabilities of the two compounds were analyzed and 1,2,4-trihydro-1,2,4-triazol-5-one was found to be more stable than 2,3,4-trihydro-1,2,4-triazol-5-one, which was consistent with experimental results.

Hydroxylammonium 3-dinitromethanide-1,2,4-triazolone exhibits exceptional properties compared to its parent acid, 3-dinitromethyl-1,2,4-triazolone; namely higher density  $\rho = 1.91 \text{ g/cm}^3$  at 298 K, superior detonation performance ( $v_D = 8946 \text{ m/s}$ ), and improved thermal, impact, and friction stabilities [437]. The solid-state structure features of the new energetic salt were investigated by XRD. This revealed  $\pi$ -stacking and hydrogen-bonding interactions that contribute to closer packing and higher density.

1,2,4-Triazolidine-3,5-diones, urazoles, are five-membered heterocycles with three nitrogen atoms and two carbonyl groups. Urazine, 4-aminourazole, 4-amino-1,2,4-triazolidine-3,5-dione,  $C_2H_4N_4O_2$ , is an easily accessible heterocycle from low-cost starting materials. Aliphatic or aromatic substituents at position four and condensation with trinitromethane or trinitroethanol lead to new energetic materials [438]. Urazine exists in two tautomeric forms.

4-Amino-1,2,4-triazolidine-3,5-dione

4-Amino-1,2,4-triazole-3,5-diol

### 8.14 3-Nitro-1,2,4-triazole-5-one

A thoroughly investigated high-density energetic material derived from triazolone is 3-nitro-1,2,4-triazol-5-one, also known as 3-nitro-1,4-dihydro-1,2,4-triazol-5-one,  $C_2H_2N_4O_3$ , NTO, CAS RN [932-64-9], 5-oxo-3-nitro-1,2,4-triazole, 5-nitro-2,4-dihydro-3*H*-1,2,4-triazol-3-one, 5-nitro-1,2,4-triazol-3-one; 3*H*-1,2,4-triazol-3-one, 1,2-dihydro-5-nitro-; or nitrotriazolone,  $M = 130.06$  g/mol. 3-Nitro-1,2,4-triazol-5-one exists in tautomeric structures and is a weak acid.

3-Nitro-1,2,4-triazol-5-one is a thermally stable, relatively insensitive explosive that has also been considered as an ingredient in solid propellants and gas generants. It forms salts with alkali metal hydroxides and strong organic bases. The current section summarizes only preparation and physical, chemical, and safety properties. Most of the work done on NTO during the past three decades has been for its application as an explosive. However, the information that is now available is also useful for its potential use as a solid propellant ingredient. This is one reason why this chapter on NTO is so detailed and contains a lot of new information gathered from the literature. NTO has high-energy release capability, high velocity of detonation, and good thermal stability and it is relatively insensitive to impact and spark discharge compared to RDX.

There are only a few chemicals like NTO that have lain dormant before being rediscovered for practical uses. NTO was discovered in 1905, at which time it was prepared by nitration of 1,2,4-triazol-5-one [439]. There was some renewed interest in NTO in the mid to late 1960s but none of these nor any of the subsequent chemical studies appear

to be directed to explosives. It was not until 1985 that Lee and Coburn published the first study on NTO as an explosive [440–442]. However, it was known that the French were secretly working on a new IHE as early as 1980, which was subsequently revealed in 1987 to be NTO [443–445]. In Europe, NTO is covered by the STANAG-4543 ED.1 specification.

#### 8.14.1 Preparation of NTO

NTO was first prepared by reaction of 1,2,4-triazol-5-one (TO) with fuming nitric acid [446]. Various types of nitrating agents have been used during the century which has passed since. All attempted to improve the yield, which may have eventually reached 83% if all had been done correctly. It is unusual that it would take this long to recognize the useful properties of a chemical.

The methods for the production of NTO differ mostly during the step used for the production of the precursor, TO. TO can be prepared by reaction of acetone semicarbazone with formic acid via diformylsemicarbazide (which undergoes a ring closure on heating), via semicarbazide hydrochloride with 85% formic acid

or triethylorthoformate, which gives TO in 64% yield [447]. Thermal decarboxylation of 1,2,4-triazole-5-one carboxylic acid gives TO in good yield.

3-Nitro-1,2,4-triazole-5-one (NTO) can be synthesized in a two-step process by reacting semicarbazide hydrochloride with formic acid to obtain 1,2,4-triazole-5-one and followed by nitration to NTO [448]. 3-Nitro-1,2,4-triazole-5-one (NTO) can be obtained by nitrating 1,2,4-triazole-3-one under different conditions [449]. The optimum conditions for nitration of TO were determined by varying the temperature (283–323 K = 10–50 °C), nitrating agent [HNO<sub>3</sub> with AcOH, Ac<sub>2</sub>O, (F<sub>3</sub>CCO)<sub>2</sub>O, NH<sub>4</sub>NO<sub>3</sub>; N<sub>2</sub>O<sub>4</sub> with CCl<sub>4</sub>, or ClCH<sub>2</sub>CH<sub>2</sub>Cl, N<sub>2</sub>O<sub>5</sub> with CCl<sub>4</sub> or ClCH<sub>2</sub>Cl]. The traditional method for making NTO is by nitrating 1,2,4-triazol-5-one in 70% nitric acid at a temperature of between 333 to 348 K (60 to 75 °C) [450]. The best NTO yield (81%) was achieved when diluting N<sub>2</sub>O<sub>4</sub> with CCl<sub>4</sub> [451]. The preparation of NTO can be simplified if it is done as a one-pot synthesis [452] (see also [453]).

The synthesis of 3-nitro-1,2,4-triazole-5-one was later scaled up to the 100-g batch size [454]. The operating conditions of NTO preparation were optimized by raising the reaction temperature in two stages and reducing the amount of nitrating agent. The dependence of reaction time and reaction temperature on NTO yield was determined.

The improvement of preparation technology has led to a high yield (81.8%) and excellent quality of NTO.

The synthesis of 5-nitro-1,2,4-triazol-3-one (NTO) from urea via chlorination followed by amination, formylation, and nitration was theoretically modeled, assuming the use of metal chlorides and metal oxides as catalysts to promote the reaction [455]. Reaction routes closely patterned after experimental processes were successfully reconstructed and the corresponding energy barriers were estimated for each elementary reaction. Reaction conditions different from those reported in the literature were used in fictitious reaction systems. The modeling results suggested that iron(III) chloride is a good catalyst for the chlorination reaction, iron(II) oxide is suitable for catalyzing amination, formylation, and nitration, and nitric acid is the better agent for nitration. Estimates of the comparable energy barriers for each reaction stage were considered to imply more feasible pathways for NTO synthesis that are yet to be explored.

Scaling up the production of NTO requires knowledge of the heat of reaction so that runaway reactions in the nitrator can be avoided and a proper amount of cooling is available. The heat of nitration and the heat of dissolution of 1,2,4-triazol-5-one (TO) in acidic environments were measured by differential reaction calorimetry [456]. The kinetics of nitration of TO in a 200-mL reactor were investigated by UV/Vis spectroscopy. Temperature changes were measured in a 10-L batch reactor during the TO nitration. A model of kinetics for the synthesis of NTO was proposed and it was used to simulate the phenomena occurring in the calorimeter and the reactors. The experimental data were compared with modeling results and with parameters of the Arrhenius equation for the synthesis of NTO with selected nitrating acid mixtures.

The heat release during nitration of 1,2,4-triazol-5-one (TO) in a nitric acid solution was determined using reaction calorimeters and the influence of the heats of reaction of individual steps on the total exothermic effect during the NTO manufacture process was examined [457]. Five types of thermal effects were differentiated and measured: the heat of dosing TO, the heat of dissolution of TO, the heat of reaction ( $\Delta H_r$ ), the heat of crystallization of NTO, and the heat caused by changes in concentration of nitric acid. The results showed that the  $\Delta H_r$  was the main contributor to the total exothermic heat release during synthesis processes in 66–96%  $\text{HNO}_3$ .

#### 8.14.1.1 Recrystallization of NTO

NTO was usually recrystallized from water or alcohols but this produced an undesirable crystal shape. Freshly prepared NTO is usually obtained in the form of jagged rod-like shape crystals. These readily agglomerate and become more sensitive to shock. As-prepared NTO has a crystal habit with length : diameter ratios in excess of 3 : 1. These irregular crystals had a low bulk density. Plastic-bonded explosives (PBX) blends incorporating the crystals were very viscous and difficult to pour. Several crystal modification methods were tested, including surfactants and stirring while crystallizing from aqueous solutions [458].

3-Nitro-1,2,4-triazol-5-one (NTO) is typically recrystallized in water but, unfortunately, NTO recrystallizes in jagged rod-like particles that have a tendency to agglomerate when using this method. The irregular and jagged crystal shapes produce highly variable results when mixing explosive formulations with NTO. It was discovered that NTO crystallizes from lower molecular weight alcohols (e.g., methanol, ethanol) in the form of spheroidal crystals rather than as jagged needles [459].

A study of the nucleation kinetics of spherulitic crystallization of NTO in *N*-methylpyrrolidone (NMP) and water and the influence of the solvent composition upon the metastable zone width and morphologic characteristics of the crystalline NTO showed that the metastable zone width of NTO solutions increased with the NMP content in the solvent [460]. The metastable zone width increased with increasing the cooling rate and with decreasing saturation temperature. Primary nucleation aided in the spherulitic crystallization of NTO. The induction period for nucleation was measured at different levels of supersaturation in various solvent compositions and was used to calculate interfacial energy. The interfacial energy obtained from nucleation experiments depended on the solvent composition and temperature.

Although the solubility of NTO in water at room temperature is less than 2%, solubility increases to ~10% in boiling water at 373 K. Notably, attempts have been made to recrystallize NTO from hot water. 3-Nitro-1,2,4-triazol-5-one has been recrystallized from water in an effort to prepare crystals with smaller size and narrower size distribution ranges in a batch cooling crystallizer [461–464]. Two mixing devices, i.e., a mechanically stirred system with and without ultrasound in aqueous media, were employed to compare mixing effects on the crystallization. Under ultrasound irradiation, the metastable zone width was significantly reduced by more than twofold, and the crystal size was shifted from 140–160  $\mu\text{m}$  to 50–70  $\mu\text{m}$ , with a narrower size distribution compared to the mechanically stirred system. However, in the mechanical stirrer, the mixing effect on NTO crystallization was negligible if the impeller speed was sufficient to suspend all crystals in the crystallizer. It was found that the crystal growth was not influenced by mixing. It was suggested that the NTO crystals were formed by primary heterogeneous nucleation that is common in a batch cooling system (see also [465, 466]).

NTO crystals were obtained from an NTO/H<sub>2</sub>O solution by a cooling method with ultrasound irradiation [467]. The morphology and the size distribution of NTO crystals were found to be very dependent on ultrasound frequency and sonication time. The shape of NTO crystals with a 47 kHz sonicator was cubic or tetragonal. On the other hand, the shape of NTO crystals with a 28 kHz sonicator appeared to be orthorhombic. The metastable zone width of the NTO/H<sub>2</sub>O system will decrease under ultrasound irradiation. The ultrasound effect on the metastable zone width became dominant dramatically when the cooling rate was smaller than 0.5 °C/min. In particular, at cooling rates smaller than 0.1 °C/min, the limit of the metastable zone widths with ultrasound was about 2 °C and was independent of the saturation temperature.

One of the methods to reduce the shock sensitivity of NTO is to recrystallize it and change the crystal morphology to assume a more spherical shape. More spherical (spherulitic) shapes could be obtained by cooling crystallization using a co-solvent. A very useful chapter on the crystallization of chemicals with special reference to NTO is contained in [468]. It includes nicely illustrated information on the best crystallization methods for NTO using different solvents and cooling rates.

Recrystallization of NTO in a co-solvent of water and *N*-methyl-2-pyrrolidone was performed to obtain 180  $\mu\text{m}$  spheroidal particles under conditions of rapid cooling and active stirring [469–471]. Scanning electron microscope (SEM) images showed that the spheroidal particles were rounded, dense, compact, and had no cavities. SEM images of the cross-section of particles showed that the particles were composed of needles with a diameter of several  $\mu\text{m}$  that were arranged radially outward from the center.

Very fine crystals of NTO can be obtained by recrystallizing from acetone [472]. Nano-NTO particles were prepared by a method of spray-freezing into liquid and SEM. Atomic force microscopy (AFM), XRD, TGA, and DSC analysis methods were used to characterize the particles [473]. The results showed that the NTO particles had an elongated shape with a size of 70–90 nm. With NTO particle size reduced to the nano-meter range, the XRD diffraction peaks broadened and the peak intensity weakened. Nano-NTO decomposed at a lower temperature and was less sensitive to impact stimuli compared with micro-NTO.

When using acetone as the solvent and by changing the distillation temperature, the initial concentration of the solution, and the vacuum system parameters, one can control the particle size distribution of NTO, which is separated out of the acetone solution by vacuum distillation of the solvent [474]. The experimental results showed that when the distillation temperature was at 333 K (60 °C), the vacuum in the system was 0.05–0.06 MPa. By employing vacuum distillation, one can get irregular and comparatively cubic crystal shapes, the particle size of which is around one  $\mu\text{m}$  and the size distribution range is narrow. The impact sensitivity of NTO decreased, seemingly through the process of being crystallized into ultra-fine size, while the detonation velocity increased. Another method is to operate with a solvent in the supercritical state and then precipitate the NTO crystals by suddenly injecting a non-solvent [475].

The volatile solvent re-crystallization of NTO on a glass substrate was studied to obtain the desired crystal shapes [476]. The observed phenomena confirmed that the crystal morphologies change from fractal to a cube-shaped structure due to the initial concentration increasing. This can be explained with diffusion-limited aggregation (DLA) theory. The fractal and cube-shaped structure NTO crystals were characterized by FTIR and XRD. The results showed that crystal morphology change cannot result in crystal structure transformation. It only affects its growth-oriented change. It would be difficult to predict the crystal morphology of NTO from theoretical information alone [477]. As this experience has shown, there are just too many variables.

Particles with spherical shape and specific size distribution are required for reproducible solids loading and mix fluidity during the processing of energetic mate-

rials for high explosive and rocket propellant applications. Spherical NTO of specific particle size distribution was prepared and the powders were characterized by XRD, thermal, and spectral methods [478]. The effects of spherical NTO of specific particle sizes of 150, 100, 25, 15, 10, and  $<5\mu\text{m}$  and their bi/trimodal mixtures on their micromeritic properties was measured. Based on the packability and flowability properties, bimodal mixtures with a coarse ( $150\mu\text{m}$ ) to fine ( $25\mu\text{m}$ ) ratio of 70 : 30 was found to be optimum for processing in explosive formulations. The study inferred that the spherical particle shape of NTO brings down the viscosity by about 75% for the same explosive content to binder ratio in comparison with non-spherical NTO.

### 8.14.2 Physical Properties of NTO

A very useful summary of the methods of preparation, recrystallization, and the physical properties of NTO is provided in an Australian military report [458]. It contains tables of properties and microscopic images of various crystal structures (see also [479]).

An excellent summary of all properties of NTO and many of its salts, supplemented by 85 references, was written by Singh and Felix [480]. The physical properties of NTO are summarized in Table 34.

One will note that the enthalpy of formation data is quite different. It is difficult to decide which is the most reliable data. One of the major disadvantages of NTO is its high vapor pressure and volatility. The equations for the vapor pressure of solid and liquid NTO are listed in Table 35.

NTO data on vapor pressure are shown together with thermocouple data in the high-temperature region. The Bourdon gauge data in the low-temperature region in

**Table 34:** Physical properties of NTO.

Data source: [483,484].

**Figure 9:** Vapor pressure of NTO and DAAzF as a function of reciprocal temperature. (Reprinted and modified from [484], with permission from ©2009 Elsevier; permission conveyed through RightsLink.)

Legend: Surface temperatures of burning DAAzF (1) and NTO (2) at different pressures, initial pressures in glass Bourdon gauges at decomposition of solid DAAzF (3) and NTO (4), and vapor pressure above solid NTO (line 5).

Figure 9 shows a good correlation between experimental surface temperatures in the interval of 0.4–2.1 MPa and the theoretical dependence of NTO boiling temperature on pressure. This was calculated using the heat of vaporization and at an experimental boiling temperature of 0.5 MPa. NTO is more volatile than DAAzF, which happened to

be part of the same investigation. The crossing of two straight lines in Figure 9 at the melting point is a good confirmation of these calculations.

The vapor pressure of NTO can also be expressed as

$$\log p = 12.5137 + 6296.553/T,$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. The heat of sublimation is  $120.01 \pm 0.29$  kJ/mol ( $28.71 \pm 0.07$  kcal/mol) [485].

#### 8.14.2.1 Solubility and Solutions of NTO

NTO is nearly insoluble in water and is more soluble in methanol than in ethanol or propanol. The solubility of NTO in  $n$ -alkanols decreases with an increasing chain length of the hydrocarbon chain. A richly illustrated account of detailed solubility investigations for NTO in solvent mixtures and multi-phase systems is provided in [468]. The nucleation behavior, interfacial energy, seed crystals, effects of supersaturation, and the effects of cooling rates on crystal growth kinetics were studied in several solvent systems. Best results were obtained with water/ $N$ -methylpyrrolidone mixtures.

The solubility of NTO in water or acetone at room temperature is less than 2%. Solubility increases to ~10% in boiling water at 373 K. The solubility in water at 278 K (4.85 °C) is 0.72%, at 292.1 K (18.95 °C) it is 1.28%, and at 316.45 K (43.3 °C) it is 2.6%.

#### 8.14.2.2 Thermodynamic Properties of NTO

##### Heat Capacity of NTO

The heat capacity of NTO was determined using a continuous  $C_p$  mode of a microcalorimeter (Micro-DSC III) [486]. In the temperature range of 283 to 353 K, the heat capacity of NTO follows a linear relation with temperature, as expressed by the equation

$$C_p = 0.2806 + 2.7103 \times 10^{-3} T,$$

where  $C_p$  is the molar heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin. The standard molar specific heat capacity of NTO was  $141.53 \text{ J mol}^{-1} \text{K}^{-1}$  at 298.15 K. Using the determined relationship of  $C_p$  with temperature  $T$ , thermodynamic functions (enthalpy, entropy, and Gibbs free-energy) of NTO between 283 and 353 K (relative to the standard temperature 298.15 K) were derived through thermodynamic relationships. The time of the thermal decomposition from initialization to thermal explosion (adiabatic time-to-explosion) was between 1.95 and 1.99 s depending on the heating rate. Another source [481] gives the heat capacity in the range from 320 to 420 K as

$$C_p = 0.00386T - 0.278,$$

where  $C_p$  is the molar heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin.

### Enthalpy of Formation of NTO

The standard molar enthalpies of formation of 1,2,4-triazol-5-one and 3-nitro-1,2,4-triazol-5-one have been determined from measurements of their energies of combustion in oxygen as  $-142.4 \pm 0.7$  kJ/mol and  $-129.4 \pm 1.1$  kJ/mol, respectively [481]. From measurements of the enthalpies of neutralization of 3-nitro-1,2,4-triazol-5-one with NaOH(aq) and KOH(aq), the enthalpies of formation of the crystalline sodium and potassium salts have been determined as  $-362.6 \pm 1.2$  kJ/mol and  $-385.1 \pm 1.1$  kJ/mol, respectively.

The Gibbs free-energy and entropy change of the NTO anion in aqueous solutions and the enthalpy change of the system  $[\text{Me}^{n+}(\text{G}) + n\text{NTO}^{-}(\text{G}) + m\text{H}_2\text{O}(\text{G})]$  were obtained for several rare-earth metal salts of NTO [487].

Gas-phase enthalpies of formation for NTO, 1,1-diamino-2,2-dinitroethene (=DADNE), LLM-105, TNT, RDX, TATB, HMX, and PETN were calculated using quantum composite methods [488]. Calculations for HMX and PETN hitherto represent the largest molecules attempted with these methods. Some calculations were close to one another, with a larger difference found between other methods. The mean absolute deviations between average experimental values and calculations were 12 to 50 kJ/mol (3 to 12 kcal/mol).

Two values were reported for the enthalpies of formation of NTO in both gas and solid phases. The values for the enthalpies of formation of NTO in gas phase were  $\Delta H_f(\text{G}) = -13.39$  kJ/mol =  $-3.2$  kcal/mol and  $-23.85$  kJ/mol =  $-5.7$  kcal/mol. In the solid phase, they were  $\Delta H_f(\text{S}) = -129.4$  kJ/mol =  $-30.927$  kcal/mol. From both the values, the enthalpy of sublimation of NTO can be calculated. Additionally, according to these data, the lattice energy of NTO becomes  $-110.46$  or  $-121.02$  kJ/mol [481]. A heat of NTO vaporization ( $82.4$  kJ/mol =  $19.7$  kcal/mol) was obtained as a difference between a heat of sublimation of  $110.5$  kJ/mol =  $26.4$  kcal/mol and a heat of melting of  $28.0$  kJ/mol =  $6.7$  kcal/mol. Heat of sublimation was calculated from the enthalpies of formation of solid ( $129.4$  kJ/mol =  $30.93$  kcal/mol) and gaseous NTO ( $13.4$  and  $23.8$  kJ/mol =  $3.2$  and  $5.7$  kcal/mol).

The temperature dependence of vapor pressure above solid NTO was obtained using initial vapor pressures of NTO measured in glass Bourdon gauge experiments on NTO decomposition. The heat of sublimation was  $110.5$  kJ/mol ( $26.4$  kcal/mol), calculated earlier from thermodynamic data, or  $107.9$  kJ/mol ( $25.8$  kcal/mol), calculated from experimental data [489].

Comparisons of the activation energies and frequency coefficients for the sublimation of NTO determined in a TGA apparatus with the activation energy for decomposition of NTO determined by T-jump/FTIR are summarized in Table 36 [490]. This illustrates that the low activation energies reported by some investigators were actually due to sublimation and not decomposition. A heat of melting of  $28.0$  kJ/mol ( $6.7$  kcal/mol =  $51.5$  cal/g) was calculated from NTO solubility in nitric acid solutions [491].

**Table 36:** Kinetics of NTO sublimation and decomposition.

| Activation energy |          | Pre-exponential factor | Temperature range | Method             |
|-------------------|----------|------------------------|-------------------|--------------------|
| kJ/mol            | kcal/mol | ln A, s <sup>-1</sup>  | K                 |                    |
| Sublimation       |          |                        |                   |                    |
| 107.9             | 25.8     | 29.2                   | 407–436           | Isothermal TGA     |
| 119.7             | 28.6     | 31.1                   | 407–448           | Non-isothermal TGA |
| 130.1             | 31.1     | 30.1                   | 453–503           | Non-isothermal TGA |
| Decomposition     |          |                        |                   |                    |
| 364               | 87.1     | 74.8                   | 562–572           | T-jump/FTIR        |

Data source: [490].

### 8.14.2.3 Molecular Structure of NTO

Manchot and Noll incorrectly attributed the molecular structure of NTO to be the hydroxy tautomer 5-hydroxy-3-nitro-1,2,4-triazole [439]. However, the stable room temperature configuration is not the C–OH hydroxy tautomer. The *aci* forms with a C–OH group and may form as intermediates during decomposition of NTO.

MO calculations were performed for several possible tautomers of 1,2,4-triazol-5-one and 3-nitro-1,2,4-triazol-5-one [492]. Calculations were also performed for some conjugate bases of these compounds. The results showed the *1H,4H* tautomer to be most stable. 5-hydroxy-*1H*-1,2,4-triazole and 3-nitro-5-hydroxy-*1H*-1,2,4-triazole were found to lie between 39.3 and 31.4 kJ/mol (9.4 and 7.5 kcal/mol), respectively, thus higher in energy than the corresponding *1H,4H* isomer. It was believed that the calculations may overestimate this relative energy by perhaps 4–12 kJ/mol (1–3 kcal/mol). The calculations also predicted that deprotonation is most likely at N4 of the lowest energy triazolone, but is almost equally likely at N1 and N4 for the corresponding nitrotriazolone (although the N4 position seems slightly favored). In the conjugate bases, a significant contribution from resonance participation of the nitro group was found. It was difficult to predict the site of electrophilic substitution in the triazolone when using the electrostatic potential (see also [493]).

The crystal structure of the  $\beta$  form of NTO has been determined by single-crystal XRD [494]. The unit cell is monoclinic, space group  $P2_1/c$ , with  $a = 9.326 \text{ \AA}$ ,  $b = 5.515 \text{ \AA}$ ,  $c = 9.107 \text{ \AA}$ ,  $\beta = 100.77^\circ$ ,  $\rho_c = 1.878 \text{ g/cm}^3$ . There are four molecules in the cell. An infinite extension of H-bonding in two-dimensional sheets occurs in the monoclinic form. Bond lengths and angles all have normal values. Efforts have been made to determine the crystal structure of  $\alpha$ -NTO. However, the structure was refined only to a low degree of accuracy. This was probably due to interference from twinning about the crystal needle axis. The unit cell is triclinic, space group  $P\bar{1}$ , with unit cell parameters of  $a = 5.12 \text{ \AA}$ ,  $b = 10.30 \text{ \AA}$ ,  $c = 17.9 \text{ \AA}$ ,  $\alpha = 106.7^\circ$ ,  $\beta = 97.70^\circ$ ,  $\gamma = 90.2^\circ$ ,  $\rho_c = 1.92 \text{ g/cm}^3$ . There are eight molecules in the cell. Ribbons of molecules formed by a relatively strong network of hydrogen bonds were observed.  $\alpha$ -NTO is the stable, dominating form.

A study of the tautomerization and ionization of NTO using MO self-consistent field (SCF) and Møller-Plesset (MP2) theories in parallel with DFT examined structures of the NTO anion, which compared well with the reported structure of NTO in its diaminoguanidinium salt [495]. The calculated IR frequencies compared well with those observed for crystalline NTO. The NTO anion was found to be more aromatic than the NTO molecule. Comparisons of bond lengths, calculated proton chemical shifts, and magnetic susceptibility anisotropies showed that the enol tautomers are more aromatic than NTO, which accounts for their enhanced stabilities.

The electron density and related properties of the quasi-stable  $\beta$  form of 5-nitro-2,4-dihydro-3*H*-1,2,4-triazol-3-one (NTO; space group  $P2_1/c$ ) have been determined from a low-temperature (100 K) XRD experiment, allowing calculation of the electron density, Laplacian, and electrostatic potential distributions [496]. The bonding critical weak points and the molecular dipole moment of 3.2 D were also obtained. NTO in the vapor phase may exist as dimer or as clusters of several molecules from which the decomposition originates [497].

The crystal structure of the metastable  $\beta$  form of 5-nitro-2,4-dihydro-3*H*-1,2,4-triazol-3-one ( $\beta$ -NTO, monoclinic,  $P2_1/c$ ) was investigated at five temperatures in the range of 100–298 K using single-crystal XRD [498]. A second-rank thermal expansion tensor has been determined to describe the thermal behavior of the crystal during warming and cooling. The most significant thermal expansion is in a plane that is almost perpendicular to the planes of all NTO molecules. Perpendicular to the plane of maximal thermal expansion, a modest thermal contraction takes place. Both thermal expansion and contraction of the crystal lattice indicated anharmonicity of the atomic thermal motion. The experimental thermal variation of the unit-cell parameters was in qualitative agreement with that previously obtained from MDs calculations. Rigid-body analysis of the molecular thermal motion was performed using the libration and translation second-rank tensors. Although the translation part of the thermal motion was not strongly anisotropic, the largest displacements of the NTO molecules were oriented in the plane of maximal thermal expansion of the crystal and had significant anharmonic components. The libration motion was more anisotropic, and the largest libration, as well as the largest translation principal axes, were directed along the C5–N5 bond in each NTO molecule.

The kinetic, potential, and electronic energy distributions in NTO were calculated from the experimental electron density using DFT functionals [499]. The spatial distribution of the electronic energy density was shown to be a useful descriptor of the chemical bonding and intermolecular interactions in this energetic molecule.

A DFT with different basis sets was applied to the study of 3-nitro-1,2,4-triazole-5-one (NTO) in both gaseous dimer and its bulk state [500]. The binding energies have been corrected for the basis set superposition errors. Six stable dimers (II–VII) were located. The corrected binding energy of the most stable dimer VII was predicted to be  $-53.66$  kJ/mol. It was found that the structures of the more stable dimers (V–VII) were associated through the hydrogen bonding interaction between the carbonyl

oxygen and the azole hydrogen of 3-nitro-1,2,4-triazole-5-one. The changes of Gibbs free-energies ( $\Delta G$ ) in the processes from the monomer to the dimers at 298.15 K were 8.51, 0.90, 0.35, -8.74, -10.67, and -11.06 kJ/mol for dimers from II to VII, respectively. Dimers V-VII possessing cyclic structures can be spontaneously produced from the isolated monomer at room temperature. Judged from the value of the band gap of 4.0 eV, it can be predicted that NTO is an insulator. Most atoms in NTO, with the exception of the C5 atom and nitro atoms, make up the upper valence bands. In contrast, the lower conduction bands mainly consist of the nitro N and O atoms. The population of the C-NO<sub>2</sub> bond is much less than those of the other bonds and the detonation may be initiated by the breakdown of this bond.

The fully optimized molecular geometries, electronic structures, and energies of 3-nitro-1,2,4-triazol-5-one and three isomers have been obtained by using DFT computational methods [501]. Three transition states (TS1, TS2, TS3) of hydrogen migration reactions have been located and confirmed by the IRC method, and the tautomerization process of NTO tautomers has been investigated. The results showed that one reaction is a primary path of NTO tautomerization, which has a reaction barrier of 122 kJ/mol.

In the vapor phase, NTO molecules can associate to form dimers. Six optimized stable NTO dimers found on the potential energy surface and their electronic structures have been obtained by using a DFT computational method [502]. The intermolecular interaction energy was calculated with basis set superposition error correction (BSSE) and zero-point energy correction. The greatest corrected intermolecular interaction energy of the dimer was -53.66 kJ/mol. It was found that the strong hydrogen bonds contribute to the dimers dominantly, while the binding energies are not only determined by hydrogen bonding. The dimerization process can occur spontaneously at lower temperatures or room temperature.

Certain isomeric compounds of NTO and their tautomers have been investigated by performing DFT calculations and also *ab initio* calculations. The optimized geometries, vibrational frequencies, electronic structures, and some thermodynamic values for the presently considered NTO isomers have been obtained in their ground states [503, 504]. Predicted detonation performances were evaluated by the K-J equations, based on the calculated densities and HOF values. The homolytic BDE of N-NO<sub>2</sub> and C-NO<sub>2</sub> scission for the molecules were calculated. The aromatic character of NTO and its isomers and tautomers were investigated by performing calculations using the gauge-invariant atomic orbital approach.

In trying to elucidate the stable forms of NTO, including its tautomers and anions, the geometries and properties of all compounds were calculated using DFT and quantum chemical methods [505]. Calculations were carried out for both the gas phase and for aqueous solutions. The chemical stability of these species was evaluated in terms of the Gibbs free-energy change. Two different solvation models were applied. Calculations showed that the overall differences in the results obtained using these two solvation models were negligible for all species considered. All possible NTO tautomers

were examined, and the results were in good agreement with previous studies performed in the gas phase. To estimate the acidic properties of NTO, anions of several NTO tautomers were analyzed. In addition to this,  $pK_a$  values were calculated using different approaches. When compared with available experimental data, it was found that the conductor-like screening model for real solvents leads to a more accurate estimation of the  $pK_a$  value than other methods, but it was proven that the pattern of deprotonation energy was correctly estimated (see also [506]).

#### 8.14.2.4 Optical Properties of NTO

NTO exists in two polymorphic forms:  $\alpha$ -NTO and  $\beta$ -NTO. The IR and Raman spectra of NTO are demonstrated in Figures 10 and 11.

**Figure 10:** IR (top) and Raman (bottom) spectrum of NTO. (Reproduced and modified from [507] with permission from ©2004 American Chemical Society; permission conveyed through RightsLink.)

The IR band assignments to molecular vibrations demonstrated in Figure 11 are listed in Table 37. NTO has the  $-\text{NH}-\text{C}=\text{O}-\text{NH}-$  amide grouping in the ring, which gives rise to the characteristic absorption of the  $\text{C}=\text{O}$  bond at  $1720\text{ cm}^{-1}$ . The bands at  $1550$ ,  $1360$ , and  $790\text{ cm}^{-1}$  can be assigned to the asymmetric, symmetric, and stretching deformation of the  $-\text{NO}_2$  group.

**Figure 11:** Infrared spectrum of NTO. (Reprinted and modified from [508], with permission from ©1994 Elsevier; permission conveyed through RightsLink.)

**Table 37:** IR spectral assignments of NTO.

| Wavenumber, cm <sup>-1</sup> | Assignment                                             |

| 690m                         |                                                        |
| 610m                         |                                                        |

Key: m, medium; s, sharp; sh, shoulder; w, weak.

Data source: [508].

The extraordinary thermal stability of NTO is due to the arrangement of its atoms. The vibrations of atoms against each other can lead to decomposition. However, before that point of breakup, infrared spectra can help to identify which atoms in the molecule cause which IR absorption band and which constitute the weakest link. Isotope labeling in NTO facilitates the assignment of absorption bands to certain locations in the molecule. The IR and Raman spectra of NTO and its compounds labeled

with the stable isotopes  $^{15}\text{N}$ ,  $^{13}\text{C}$ , and deuterium (D) [such as NTO- $^{15}\text{NO}_2$ , NTO- $^{13}\text{C}(3)$  or NTO-D] were measured in the region of  $100\text{--}3500\text{ cm}^{-1}$  [507]. Vibrational motions were experimentally assigned by using isotopic vibrational shifts. In addition, theoretical calculations were performed to assign those vibrational bands with good agreement of experimental and theoretical data. Furthermore, the experimental and calculated results indicate that the C—O bond length of NTO in the crystal state is longer than that of an isolated molecule in the gas phase because of intermolecular hydrogen bonding.

The Raman spectra of the  $\alpha$  form of NTO were measured in a high-pressure vessel diamond anvil cell at pressures up to 27.6 GPa [509]. In general, Raman bands showed a blue shift because of the nature of the molecule packing (which has a high-pressure effect) but some particular bands exhibited a red shift, disappearance, split, or slight shifting. Those red-shifting bands are the result of hydrogen bonds, i.e., carbonyl and amino groups that are likely to work as a stabilizer against stimuli to the molecule or crystal. This stabilizing nature might characterize the insensitivity of NTO. Computations predicted that the peak frequency in the power spectrum of the CO-stretching vibration should exhibit a red shift with an increase in pressure up to 10.0 GPa, while the peak intensity should considerably decrease under the same pressure process because this bond length increases with an increase in pressure up to the aforementioned GPa. At a pressure of  $>20.0$  GPa, a blue shift appeared. These results of the molecular dynamics calculations were in good agreement with experimental data.

### 8.14.3 Chemical Properties of NTO

The oxygen balance of NTO is  $-24.6\%$ . An energetic compound does not have to be stoichiometric with an oxygen balance of  $0\%$  to be a very useful explosive and propellant ingredient.

#### 8.14.3.1 Reactions of NTO with Other Compounds

NTO is amphoteric and can form salts with both strong bases and strong acids.

NTO Cation

NTO Anion

The acid constants are  $pK_{a1} = 3.76$  and  $pK_{a2} = 11.25$ . Owing to the acidic nature of NTO, it forms salts with a large number of metals as well as aromatic and aliphatic amines, which are also useful in propellants. The ease of formation of a large number of salts offers a chance of making a wide variety of compounds that can be tailored to specific applications. Other sources reported the  $pK_a$  of NTO as 3.67 [510].

The reaction of NTO with ammonia would form an ammonium salt and the association with water would form a hydrate. Intermolecular interactions between NTO and ammonia or water were examined by computational chemistry methods [511]. The energy levels of two fully optimized geometries of  $\text{NTO} \cdots \text{NH}_3$  complexes have been calculated using a DFT method [512]. The intermolecular interaction energy was calculated with a zero-point energy correction and a BSSE. The greatest corrected intermolecular interactions of the  $\text{NTO} \cdots \text{NH}_3$  complexes were  $-3758 \text{ kJ/mol}$ . Electrons in complex systems transfer from  $\text{NH}_3$  to NTO. The strong hydrogen bonds contribute to the interaction energies dominantly. Natural bond orbital (NBO) analysis was performed to reveal the origin of the interaction. Based on vibrational analysis, the changes of thermodynamic properties from the monomer to complexes with temperatures ranging from 200 to 800 K have been obtained using a statistical thermodynamic method. It was found that two  $\text{NTO} \cdots \text{NH}_3$  complexes can be produced spontaneously from NTO and  $\text{NH}_3$  at normal temperatures.

#### 8.14.3.2 Salts of NTO

The most complete summary of properties of salts of NTO, including metal salts and salts of organic nitrogen-containing bases, was compiled by Singh and Felix in 2002 [513]. It includes properties of 50 salts and the information is backed up by 68 references.

#### Metal Salts of NTO

The metal salts of NTO are arranged here in the sequence of their column group numbers in the International Union of Pure and Applied Chemistry (IUPAC) periodic table of elements. Multi-element studies that do not fit into an individual group are discussed first.

Twenty-six metal salts of 3-nitro-1,2,4-triazol-5-one were prepared and characterized by using elemental analysis, DSC, TGA,  $^{13}\text{C}$ -NMR, XPS, electric conductivity, IR,

and powder XRD [514]. The results confirmed that these salts have a general formula as  $M(\text{NTO})_m \cdot n\text{H}_2\text{O}$ . Additional publications on NTO salts were in [515, 516]. Lead, copper, and ammonium salts of NTO can be used as burning rate catalysts in solid propellants [517].

It was attempted to establish a relationship between the standard enthalpy of formation and the standard enthalpy of formation divided by the exothermic denitration decomposition peak absolute temperature [518]. 3-Nitro-1,2,4-triazol-5-one and its salts are insensitive energetic materials with wide application prospects. The preparation, characterization, and application of NTO and its salts were reviewed [519].

The synthesis and properties of 3-nitro-1,2,4-triazol-5-one (NTO), including synthesis methods, crystal structure, quantum chemistry, thermal behaviors, and toxicity were reviewed in detail [520]. The molecular structure and thermodynamic properties of 21 types of NTO salts with alkali, alkaline earth, transition metals, and rare-earth metals were measured. The thermal decomposition products of NTO alkali metal salts were identified as carbonates with Li, Na, and K, and those of Rb and Cs salts of NTO were carbonate, metal oxide, and polymers. A relationship between the enthalpy of activation ( $\Delta H_{\text{act}}$ ) and the value of the peak temperature during decomposition of several NTO alkali metal salts was derived with 73 data points.

The molar enthalpies of dissolution in water of a variety of NTO salts of the general formula  $\text{Me}(\text{NTO})_n \cdot m\text{H}_2\text{O}$  (Me = Ba, Li, Ca, Na, Co, Mg, Ce, Pr, Gd, Tb, Dy, Y, Yb) were measured in a microcalorimeter. Five empirical formulae describing the differential enthalpy of dissolution, standard molar enthalpy of dissolution, relative apparent molar enthalpy, relative partial molar enthalpy, and enthalpies of dilution in water of these metal salts of NTO were obtained [521, 522]. Metal salts of NTO have been evaluated as burning rate modifiers for AN/hydroxy-terminated polybutadiene (HTPB) propellants [523]. The following sections describing the metal salts of NTO are arranged by the group number of the metal in the periodic table of elements.

### Group 1 Metals: Li, Na, K, Rb, Cs

The thermal stability of K, Cu, Pb, and  $\text{NH}_4$  salts of NTO has been described by [524, 525]. 1,2,4-Triazol-5-one (TO) and 3-nitro-1,2,4-triazol-5-one (NTO) and the mono- and dilithium salts of NTO were prepared and characterized by TGA and  $^{13}\text{C}$  and  $^{15}\text{N}$  NMR spectra [526]. XRD crystal data of lithium salts of NTO revealed solid-state crystal structures that had not been reported previously.  $^{13}\text{C}$  and  $^{15}\text{N}$  NMR verified solution state anion forms other than those that do exist in the solid state for  $\text{Li}(\text{NTO}) \cdot 2\text{H}_2\text{O}$  and  $\text{Li}_2(\text{NTO}) \cdot 5\text{H}_2\text{O}$ .

From measurements of the enthalpy of solution of metal salts of 3-nitro-1,2,4-triazol-5-one (NTO) in water, the standard enthalpies of formation of  $\text{KNT} \cdot \text{H}_2\text{O}$ ,  $\text{Ba}(\text{NTO})_2 \cdot 3\text{H}_2\text{O}$ ,  $\text{LiNTO} \cdot 2\text{H}_2\text{O}$ ,  $\text{Ca}(\text{NTO})_2 \cdot \text{H}_2\text{O}$ , and  $\text{Gd}(\text{NTO})_3 \cdot 7\text{H}_2\text{O}$  were determined as  $-(676.9 \pm 2.6)$  kJ/mol,  $-(1627.0 \pm 2.5)$  kJ/mol,  $-(966.63 \pm 2.2)$  kJ/mol,  $-(1905.5 \pm 4.4)$  kJ/mol, and  $-(3020.1 \pm 6.4)$  kJ/mol, respectively [527]. From measurements of the enthalpy of precipitation of  $\text{KNT} \cdot \text{H}_2\text{O}$  crystal with  $\text{Pb}(\text{NO}_3)_2(\text{aq})$ ,

$\text{CuSO}_4(\text{aq})$  and  $\text{Zn}(\text{NO}_3)_2(\text{aq})$ , the standard enthalpies of formation of  $\text{Pb}(\text{NTO})_2 \cdot \text{H}_2\text{O}$ ,  $\text{Cu}(\text{NTO})_2 \cdot 2\text{H}_2\text{O}$  and  $\text{Zn}(\text{NTO})_2 \cdot \text{H}_2\text{O}$  were determined as  $-(247.4 \pm 5.9) \text{ kJ/mol}$ ,  $-(712.1 \pm 5.4) \text{ kJ/mol}$  and  $-(628.8 \pm 5.7) \text{ kJ/mol}$ , respectively.

$\text{Li}(\text{NTO})(\text{H}_2\text{O})_2$  was prepared by mixing 3-nitro-1,2,4-triazol-5-one (NTO) aqueous solution and lithium hydroxide aqueous solution and its thermal decomposition was studied by DSC, TG/DTG, and IR methods [528]. The kinetic parameters were obtained from the analysis of the DSC and TG/DTG curves using the Kissinger method, the Ozawa method, the differential method, and the integral method. The most probable mechanism function for the thermal decomposition of the first stage was suggested by comparing the kinetic parameters. The critical temperature of thermal explosion ( $T_b$ ) was 562 K (289 °C).

The lithium and potassium salts of NTO were prepared and characterized by elemental analysis, metal content determination, and FTIR [529]. The DSC thermogram indicated that the Li and K salts of NTO undergo exothermic decomposition in the temperature range of 530–633 K (257–360 °C). The TGA weight loss pattern revealed loss of water for Li/K salts of NTO in the temperature range of 388–428 K (115–155 °C). The compounds were insensitive to impact and friction (impact sensitivity, height of 50% explosion >170 cm, and friction insensitivity was negative at up to 36 kg<sub>f</sub>) stimuli despite the fact that even the parent molecule of NTO salts is in the hazard category of 1.1. The FTIR spectra of the gaseous products evolved during TGA of NTO salts indicated the release of  $\text{NO}_2$ . The formation of products such as  $\text{LiNCO}$  and  $\text{KNCO}$  was also observed. To assess the performance as energetic ballistic modifiers, NTO salts were incorporated in AP-HTPB composite propellants. The potassium salts enhanced the burning rates of the propellants.

The potassium salts of NTO,  $\text{KNTO} \cdot \text{H}_2\text{O}$ , was prepared by mixing an aqueous solution of NTO and potassium hydroxide and characterized by TGA, elemental analysis, and IR [530]. The crystal structure of  $[\text{KNTO} \cdot \text{H}_2\text{O}]$  was determined by single-crystal XRD. The crystal is monoclinic, space group  $P2_1/n$ , with crystal unit cell parameters of  $a = 0.6408(1) \text{ nm}$ ,  $b = 0.8218(1) \text{ nm}$ ,  $c = 1.2626(1) \text{ nm}$ ,  $\beta = 100.63^\circ(1)$ ,  $V = 0.6535(1) \text{ nm}^3$ ,  $Z = 4$ ,  $D_c = 1.892 \text{ g/cm}^3$ .

### Group 2 Metals: Be, Mg, Ca, Sr, Ba

The thermal stability of the barium salt of NTO,  $\text{Ba}(\text{NTO})_2 \cdot 3\text{H}_2\text{O}$ , was measured by TGA and DSC [531]. This salt was evaluated as a combustion catalyst and ballistic modifier for solid propellants.

The salt  $[\text{Sr}(\text{NTO})_2(\text{H}_2\text{O})_4]_2 \cdot 4\text{H}_2\text{O}$  was prepared by mixing an aqueous solution of NTO with an excess of strontium carbonate and crystallizing the salt from the filtrate [532]. The single-crystal structure was determined by XRD. The crystal is monoclinic, space group  $P2_1/c$ , with crystal unit cell parameters of  $a = 1.1034(1) \text{ nm}$ ;  $b = 2.2742(2) \text{ nm}$ ,  $c = 0.63398(9) \text{ nm}$ ,  $\beta = 101.798(13)^\circ$ ,  $V = 1.5573(4) \text{ nm}^3$ ,  $D_c = 1.936 \text{ g/cm}^3$ ,  $Z = 2$ . From measurements of the enthalpy of solution in water of  $[\text{Sr}(\text{NTO})_2(\text{H}_2\text{O})_4]_2 \cdot 4\text{H}_2\text{O}$  at 298.15 K, the standard enthalpy of formation, lattice

energy, lattice enthalpy, and standard enthalpy of dehydration have been determined as  $-(2545.2 \pm 4.7)$ ,  $-2114$ ,  $-2136$  and  $67.2$  kJ/mol, respectively.

Four alkaline earth metal salts of NTO,  $\text{Mg}(\text{NTO})_2 \cdot 8\text{H}_2\text{O}$ ,  $\text{Ca}(\text{NTO})_2 \cdot 4\text{H}_2\text{O}$ ,  $\text{Sr}(\text{NTO})_2 \cdot 5\text{H}_2\text{O}$ , and  $\text{Ba}(\text{NTO})_2 \cdot 3\text{H}_2\text{O}$ , have been prepared from metal carbonates and NTO in aqueous suspensions at 333 K (60 °C) and characterized by TGA, DTA, and explosion delay measurements [533]. In the TGA, mass losses occurred in three steps. Decomposition reaction pathways involving slow thermolysis (decomposition) and rapid thermolysis (explosion) have been suggested. If heated in air, the oxidation-reduction reactions near the surface of the thermolyzing material  $[\text{M}(\text{NTO})_2 \cdot n\text{H}_2\text{O}]$  seem to be responsible for the decomposition and explosion. The activation energies for the explosion were in the range of 28–34 kJ/mol.

The magnesium salt of NTO,  $[\text{Mg}(\text{H}_2\text{O})_6](\text{NTO})_2 \cdot 2\text{H}_2\text{O}$ , can be prepared by adding magnesium carbonate hydroxide to the aqueous solution of NTO [534]. The crystal structure is monoclinic with space group  $C2/c$  and unit-cell parameters  $a = 2.3101(3)$  nm,  $b = 0.6472(1)$  nm,  $c = 1.4118(3)$  nm, and  $\beta = 124.05(1)^\circ$ . The standard molar enthalpy of formation is  $-(3015.4 \pm 4.2)$  kJ/mol.

In a similar study, the salt  $[\text{Mg}(\text{H}_2\text{O})_6](\text{NTO})_2 \cdot 2\text{H}_2\text{O}$  was prepared by adding magnesium carbonate hydroxide to the aqueous solution of NTO and its thermal decomposition mechanism was studied by DSC, TGA/DTG, and IR [535]. The results of a quantum chemical calculation showed that the bonds between the co-ordinate waters and the Mg atom have a covalent character to a certain extent. The net charges on nitrogen atoms of the NTO ring appeared to be negative while the nitrogen atom on the nitro group ( $-\text{NO}_2$ ) appeared to be positive, which indicated that  $-\text{NO}_2$  will lose first when the complex is heated. This result was in agreement with that of a thermal decomposition experiment. A calcium carbonylhydrazide complex ion,  $[\text{Ca}(\text{NH}_2\text{NHCONHNH}_2)_2(\text{H}_2\text{O})]$ , can form a stable salt with two mols of NTO using an aqueous solution of calcium 3-nitro-1,2,4-triazol-5-onate and carbonylhydrazide [536].

### Group 3: Sc, Y, La, Lanthanides

Several rare-earth metal (Pr, Nd, Sm) NTO salt hydrates were prepared, and the thermal stability was characterized by Xie et al. [537].

### Group 7–10: Mn, Fe, Co, Ni

The preparation and thermal decomposition mechanism of the Mn(II), Co(II), and Ni(II) salts of 3-nitro-1,2,4-triazol-5-one was studied [514, 538]. Six energetic transition metal salts of NTO  $[\text{M}(\text{NTO})_2]$ , with  $\text{M} = \text{Mn, Fe, Co, Ni, Cu, and Zn}$ , were prepared and characterized by TGA, DSC, and explosion delay measurements [539]. The melting points of the salts varied over a range of between 411 and 633 K (138–360 °C). Most salts decomposed before melting. The Fe(II) salt of NTO was the thermally most stable salt in this group. Several salts exploded in the TGA quickly after losing only 20–30% of the initial mass. In the DTA, the activation energies of the transition metal salts were lower than that of NTO, indicating that the metal cations catalyze the NTO de-

composition. It seems that the explosive behavior of NTO is quite enhanced due to the transition metal ions as these are known to be good oxidation catalysts. Thus, these salts may be explored as burning rate modifiers for solid propellants.

Single crystals of the cobalt salt of 3-nitro-1,2,4-triazol-5-one,  $[\text{Co}(\text{H}_2\text{O})_6](\text{NTO})_2 \cdot 2\text{H}_2\text{O}$ , were prepared and the crystal structure was determined by XRD [540]. The crystals were monoclinic with space group *Cc* and unit cell parameters of  $a = 2.3163(2)$  nm,  $b = 0.6451(1)$  nm,  $c = 1.4123(1)$  nm,  $\beta = 123.96(1)^\circ$ ,  $V = 1.7504(3)$  nm<sup>3</sup>, and  $Z = 4$ . From measurements of the enthalpy of solution in water at 298.15 K, the standard enthalpy of formation was calculated as  $-(2594.7 \pm 4.5)$  kJ/mol.

Several Co/Cu/Ni/Fe salts of NTO were prepared and characterized [541]. All of the salts exhibited exothermic decomposition in the DSC. The FTIR spectra of the gaseous products evolved during TGA of NTO salts and indicated the release of  $\text{NO}_2$  and cleavage of the NTO ring during the course of decomposition. The transition metal salts enhanced the burning rates of AP/HTPB composite propellants. The best catalytic effect was obtained with the Fe-NTO salt, which increased the burning rate by ~80% and reduced the pressure index ( $n$ ) to 0.18 (at 2 to 9 MPa).

#### Group 11: Cu, Ag, Au

The Pb, Cu(II), K,  $\text{NH}_4^+$ , and ethylenediamine salts of 3-nitro-1,2,4-triazol-5-one were prepared, and their densities, impact sensitivities, friction sensitivities, DSC, and critical temperatures of thermal explosion were determined [542].

Under linear temperature increase conditions, the mechanisms and kinetic parameters of thermal decomposition of NTO and NTO salts of the type  $\text{M}(\text{NTO})_m \cdot n\text{H}_2\text{O}$  for  $\text{M} = \text{Cu}$ ,  $m = 2$ ,  $n = 4$ ;  $\text{M} = \text{Pb}$ ,  $\text{H}_3\text{NCH}_2\text{CH}_2\text{NH}_3$ ,  $m = 2$ ,  $n = 0$ ;  $\text{M} = \text{K}$ ,  $\text{NH}_4$ ,  $m = 1$ ,  $n = 1$ , were obtained by TGA, DSC, IR, and XRD [525]. The thermal decomposition processes of  $\text{Cu} \cdot (\text{NTO})_2 \cdot 4\text{H}_2\text{O}$  and  $\text{K} \cdot \text{NTO} \cdot \text{H}_2\text{O}$  can be divided into three stages: dehydration, ring breaking, and forming metal oxide. However, the thermal decomposition process of  $\text{Pb} \cdot (\text{NTO})_2$  occurred in only two stages because there was no crystal water.

The 3-nitro-1,2,4-triazol-5-one silver salt was synthesized by the reaction of NTO sodium salt with silver nitrate aqueous solution [543]. Its thermal stability was characterized by DSC and TGA. The decomposition process of  $\text{AgNTO} \cdot 2\text{H}_2\text{O}$  was found to be divided into four stages: dehydration process, fracture and decomposition of the nitro group, breaking of the triazole ring, and the primary formation of inorganic materials. The ultimate generation of  $\text{Ag}_2\text{CO}_3$  and the maximum decomposition temperature was about 503 K (230 °C). The ultimate decomposition product was  $\text{Ag}_2\text{CO}_3$ .

#### Group 14: Pb

The lead salt of NTO  $[\text{Pb}(\text{NTO})_2(\text{H}_2\text{O})]$  was prepared by mixing aqueous solutions of sodium 3-nitro-1,2,4-triazol-5-onate and lead nitrate [544]. It was characterized by thermal analysis, elemental analysis, <sup>13</sup>C NMR, and IR measurements. The crystal structure of  $[\text{Pb}(\text{NTO})_2(\text{H}_2\text{O})]$  was determined by single-crystal XRD analysis. The crystal belongs to space group  $P2_1/n$  with crystal parameters of  $a = 0.7284(2)$ ,

$b = 1.2166(3)$ ,  $c = 1.2310(3)$  nm,  $\angle \beta = 90.36(2)^\circ$ ,  $V = 1.0908(4)$  nm<sup>3</sup>,  $Z = 4$ , and  $D_c = 2.96$  g/cm<sup>3</sup>.

Five transition metal salts of NTO,  $[M(\text{NTO})_n] \cdot m\text{H}_2\text{O}$  (where M is Ag, Hg, Cd, Cr, and Fe and where  $n = 1, 2, 2, 3, 3$  and  $m = 1, 2, 2, 8, 2$ , respectively) were prepared and characterized [545]. The thermal decomposition of these salts was investigated by TGA, DTA, and the explosive behavior was studied in terms of explosion delay and impact and friction sensitivities. Kinetic parameters have been derived using non-isothermal TGA data and a mechanism of thermolysis has also been proposed. It seems that dehydration takes place before the evolution of NO<sub>2</sub> and the subsequent ring rupture yields metal oxide. AgNTO on the other hand yields metallic silver. Dehydration in the case of HgNTO occurred in two steps; at each step, one NTO molecule was lost. All the salts were insensitive to impact and to friction up to a pistil load of 360 N. The order of activation energy for thermal decomposition of NTO and that of the corresponding dehydrated salts obtained was: NTO > FeNTO > AgNTO > CdNTO > HgNTO > CrNTO. The synthesis of 3-nitro-1,2,4-triazole-5-one and its lead salt was scaled up to the 100-g batch size [454] (see also [546]).

#### 8.14.3.3 Salts of NTO with Nitrogen Containing Bases

Overall, we have arranged salts by the cation first and by the anion last throughout this publication. For the nitrogen base salts of NTO discussed here, we have made an exception; salts and valuable propellant ingredients are discussed together as a group with their parent anion (NTO) instead of scattering the information over several nitrogen-based cation chapters [547–549]. In addition to the seven 1-hydro-3-nitro-1,2,4-triazol-5-one (NTO) salts, Table 38 contains data for three salts of 5-nitrotetrazole (NT) and three salts of 3,5-dinitro-1,2,4-triazole (DNTr). In this publication, we have not stated whether the DSC temperature shown was the onset of an exotherm or the maximum temperature of an exotherm and whether the samples were heated under inert gas or in air. Comparing the numbers for RDX and triaminoguanidinium nitrate (TAGN) in Table 38 to other literature data for RDX and TAGN, we assume the temperature shown is the start of the exotherms because the RDX exotherm maximum occurs typically at 513 K (240 °C) and the difference between air and nitrogen is only 5°. The source of this table did not state if the drop weight impact height shown is the 50% point determined by the Bruceton up-and-down method or if it is the minimum height at which the first initiation reaction was observed in one out of ten trials. Other studies also using the Type 12 tool reported drop weight sensitivities for RDX in the range of 31 cm for the 10% firing point and 45 cm for the 50% firing point [550]. Notably, both numbers are higher than the 22 cm listed for RDX in Table 38.

Table 38: Properties of NTO salts with nitrogen-containing bases.

| Compound name                                           | Acronym | Gross formula | Molecular mass | Nitrogen content | Oxygen balance | DTA exotherm | Drop-weight impact height <sup>a</sup> | Enthalpy of formation |                              |
|---------------------------------------------------------|---------|---------------|----------------|------------------|----------------|--------------|----------------------------------------|-----------------------|------------------------------|
|                                                         |         |               |                |                  |                |              |                                        | kJ/mol                | kcal/mol                     |

### Ammonium Salts of NTO

Ammonium 3-nitro-1,2,4-triazol-5-onate, also known as 3-nitro-1,2,4-triazol-5-one,  $\text{NH}_4^+$  salt; 3*H*-1,2,4-triazol-3-one, 1,2-dihydro-5-nitro-, monoammonium salt; ANTO;  $[\text{C}_2\text{H}_1\text{N}_4\text{O}_3^-]\text{NH}_4^+$ ,  $\text{C}_2\text{H}_5\text{N}_5\text{O}_3$ ,  $M = 147.093 \text{ g/mol}$ , CAS RN [127173-68-6],  $\Delta H_f = -197 \text{ kJ/mol} = -47.1 \text{ kcal/mol} = -320 \text{ cal/g}$ , is a solid which crystallized as orthorhombic crystals, space group *P*222, with unit cell parameters of  $a = 6.281(2) \text{ \AA}$ ,  $b = 8.423(2) \text{ \AA}$ ,  $c = 12.693(5) \text{ \AA}$ , and  $\rho = 1.65 \text{ g/cm}^3$ ,  $Z = 4$  [552]. The N4 proton is more acidic than the one at N1, and deprotonation is easier from N4 than from N1.

Under linear temperature increase conditions, the mechanism and kinetic parameters of thermal decomposition of NTO and  $\text{NH}_4\text{NTO}$  were obtained by TGA, DSC, IR, and XRD [525]. The decomposition process of  $\text{NH}_4\text{NTO} \cdot \text{H}_2\text{O}$  (ANTO) occurred in three stages, which were dehydration, deamination, and the decomposition reaction of NTO which formed in the second stage. However, if the sample was sealed in a closed stainless-steel cell or if the ammonia produced in the second stage did not escape as fast as it was produced, the gaseous ammonia catalyzed the decomposition of NTO. If the DSC was conducted under static air instead of flowing air, the result would be different. Under static air conditions and heating rates of 1 and  $2^\circ\text{C/min}$ , there was a sharp exothermic peak after the two endothermic peaks in the DSC curves. The temperatures at which the exothermic peaks appeared were 535.9 and  $535.6 \text{ K}$  ( $262.8$  and  $262.5^\circ\text{C}$ ), respectively. These are close to the temperature of the decomposition peak of NTO. Under the condition of static air, and heating rates of 5, 10, and  $20^\circ\text{C/min}$ , the exothermic peaks were shifted downwards substantially and appeared at 484.6, 494.4, and  $509.6 \text{ K}$  ( $211.5$ ,  $221.3$ , and  $236.5^\circ\text{C}$ ), respectively, which represents downwards shifts of  $23$ – $58^\circ\text{C}$ . Therefore, it became clear that the mechanism of thermal decomposition in the third stage of ANTO was different from that of pure NTO explosive under high heating rate conditions. The standard HOFs at  $298.15 \text{ K}$  of the crystalline silver and ammonium salts of 3-nitro-1,2,4-triazol-5-one are  $-269.9 \pm 1.1$  and  $-47.1 \pm 1.4 \text{ kJ/mol}$ , respectively [553].

Calculations of the geometrical structure of ammonium 3-nitro-1,2,4-triazol-5-onate by semi-empirical MO showed that there are four distinguished types of intermolecular hydrogen bonding in the crystal molecular/ionic system [554]. The binding energies of  $\text{NH}_4^+\text{NTO}^-$ ,  $\text{NTO}^-/\text{H}_2\text{O}$ , and  $\text{NH}_4^+/\text{H}_2\text{O}$  are  $-964$ ,  $-572$ , and  $-61.35 \text{ kJ/mol}$  ( $-230.516$ ,  $-136.671$ , and  $-14.664 \text{ kcal/mol}$ ), respectively. The charge densities show the deprotonation ability of various nitrogens of  $\text{NTO}^-$  ion, a result that corresponded to some earlier studies.

The ammonium 3-nitro-1,2,4-triazol-5-onate molecular system, which comprises the energetic compound 3-nitro-1,2,4-triazole-5-one with its two lowest-energy conformers L1 and L2, ammonia, and water molecules, was examined by a theoretical calculation of corresponding geometrical structures and localized bonding characters [555]. With the medium (or solvent) of  $\text{H}_2\text{O}$  and  $\text{NH}_3$ , three intermolecular hydrogen bonds formed in the  $\text{NTO} + \text{NH}_3 + \text{H}_2\text{O}$  system. This lowers the overall molecular energy and stabilizes the system.

The thermal decomposition of ammonium 3-nitro-1,2,4-triazol-5-onate monohydrate  $[\text{NH}_4(\text{NTO}) \cdot \text{H}_2\text{O}]$  was studied using a combination of thermal analysis-MS and *in-situ* thermolysis cell with rapid-scan FTIR [556]. The results showed that there are two endothermic steps and one exothermic step in the decomposition process of  $[\text{NH}_4(\text{NTO}) \cdot \text{H}_2\text{O}]$ . The detected off-gas products consisted of  $\text{NH}_3$ ,  $\text{H}_2\text{O}$ ,  $\text{N}_2$ ,  $\text{CO}_2$ ,  $\text{CO}$ , and  $\text{NO}_2$ .

### Hydroxylammonium Salts of NTO

The hydroxylammonium salt of NTO was prepared by reaction of the sodium salt of NTO with HAN. The salt melted at 461–463 K (188–190 °C) and in the DSC thermogram it showed two exotherms, one at 463 K (190 °C) and another at 543 K (270 °C), [557, 558]. The diethylhydroxylammonium salt of NTO melted at 381–383 K (108–110 °C) without apparent decomposition. The *N*-methylhydroxylammonium salt of NTO melted at 430–431 K (157–158 °C) and started to decompose even before it melted. The drop weight impact sensitivity of the hydroxylammonium and diethylhydroxylammonium salts of NTO was above 200 kg cm (insensitive). Another method for preparing the hydroxylammonium salt of NTO would be the neutralization of the hydroxylamine-free base in an aqueous solution with NTO [559].

The hydroxylammonium salt of 3-nitro-1,2,4-triazol-5-one (HANTO) was synthesized by the reaction of 3-nitro-1,2,4-triazol-5-one with NaOH and then with hydroxylammonium chloride [560]. The structure was confirmed by  $^{13}\text{C}$  NMR, IR, MS, elemental analysis, and XRD. HANTO crystals are triclinic, space group  $P\bar{1}$  with crystal unit cell parameters  $a = 0.662.5(2)$  nm,  $b = 0.712.4(4)$  nm,  $c = 0.722.1(3)$  nm,  $\alpha = 68.46(4)^\circ$ ,  $\beta = 71.36(3)^\circ$ ,  $\gamma = 67.50(3)^\circ$ ,  $V = 0.286.4(2)$  nm<sup>3</sup>,  $\rho_c = 1.891$  g/cm<sup>3</sup>, and  $Z = 2$ . There are intramolecular and intermolecular hydrogen bonds in the HANTO crystal.

### Hydrazinium Salts of NTO

The hydrazinium salt of NTO,  $\text{N}_2\text{H}_5^+[\text{C}_2\text{H}_1\text{N}_4\text{O}_3^-]$ ,  $\text{C}_2\text{H}_6\text{N}_6\text{O}_3$ , HNTO,  $M = 162.108$  g/mol, is very soluble in water. Twelve salts of 3-nitro-1,2,4-triazol-5-one (ammonium, hydrazinium, guanidinium, aminoguanidinium, diaminoguanidinium, triaminoguanidinium, *N*-carbamoylguanidinium, semicarbazidium, 1,5-diamino-1,2,4-tetrazolium, 3,4,5-triamino-1,2,4-triazolium, 3,6,7-triamino-7*H*-[1,2,4]triazolo-[1,5-*c*][1,2,4]triazol-2-ium, and 4,4',5,5'-tetraamino-3,3'-bi-1,2,4-triazolium) were synthesized and fully characterized by  $^1\text{H}$  and  $^{13}\text{C}$  NMR, IR, and elemental analysis [561]. The crystal structures of two salts were determined by single-crystal XRD. All energetic salts except one exhibited excellent thermal stability, with decomposition temperatures ranging from 476 to 543 K (203 to 270 °C). The densities of salts ranged from 1.65 to 1.88 g/cm<sup>3</sup>, as measured by a gas pycnometer. Theoretical performance calculations yielded predicted detonation pressures and detonation velocities for the energetic salts, which ranged from 24.4 to 38.1 GPa and 8136 to 9575 m/s, respectively. Hydrazinium(1+) 3-nitro-1,2,4-triazol-5-onate in particular had an outstanding detonation performance ( $P_{\text{CJ}} = 38.1$  GPa,  $v_{\text{Det}} = 9575$  m/s) with a satisfactory acidity

compared to that of NTO ( $pK_a = 5.63$  versus  $pK_a = 2.37$ ). Table 39 gives a summary of the properties of ammonium and hydrazinium 3-nitro-1,2,4-triazole-5-onate and several other NTO salts of nitrogen-containing bases.

Hydrazinium(1+) 3-nitro-1,2,4-triazol-5-onate can be prepared by the reaction of 3-nitro-1,2,4-triazol-5-one in ethanol with hydrazine hydrate in ethanol. Its structure can be characterized by employing elemental analysis, FTIR, XRD,  $^{13}\text{C}$  NMR, and  $^{15}\text{N}$  NMR [562]. The formation of HNTO is due to proton transfer from the N(4) atom, and it makes a higher nitrogen content and lower acidity than NTO. The non-isothermal reaction kinetics of the main exothermic decomposition reaction of HNTO were investigated by DSC. The decomposition reaction mechanism of HNTO with  $E_a = 195.29 \text{ kJ/mol}$  and  $\log A = 19.37 \text{ s}^{-1}$  can be expressed by the equation

$$\frac{d\alpha}{dt} = 10^{18.97} (1 - \alpha) [-\ln(1 - \alpha)]^{\frac{3}{5}} e^{(-2.35 \times 10^4/T)}.$$

The critical temperature of the thermal explosion was 464–474 K, the adiabatic time-to-explosion was 262 s, the impact sensitivity was  $H_{50} = 45.7 \text{ cm}$ , and the electrostatic spark discharge sensitivity was  $E_{50} > 5.4 \text{ J}$  (no ignition). The heat capacity of HNTO for the temperature range  $283 \text{ K} < T < 353 \text{ K}$  can be expressed by the equation

$$C_p = 0.1839 + 1.9966 \times 10^{-3} T$$

where  $C_p$  is the heat capacity in  $\text{J g}^{-1} \text{ K}^{-1}$  and  $T$  is the temperature in kelvin. The standard molar heat capacity  $C_p$  at 298.15 K was determined as  $79.44 \text{ J mol}^{-1} \text{ K}^{-1}$ .

The thermal decomposition mechanism of hydrazinium 3-nitro-1,2,4-triazol-5-onate (HNTO) was studied by DSC, TGA-DTG, and *in-situ* thermolysis/reflectance spectroscopy-FTIR (RSFTIR) [563]. The decomposition of HNTO was later simulated by MO quantum mechanical calculations. The results predicted that HNTO has two exothermic decomposition reaction stages. First, the nitro group breaks away from the HNTO molecule. Following this, the hydrazine group breaks away almost simultaneously with the carbonyl group, accompanying the azole ring which breaks in the first stage, which is then followed by second stage disintegration. The order of C–N bond strength is  $\text{C3–N4} > \text{N2–C3} > \text{N4–C5} > \text{N1–C5}$ . The weakest bond in NTO<sup>−</sup> is the N7–C3 bond.

A co-crystallized oxidizer composed of hydrazinium 3-nitro-1,2,4-triazol-5-onate (HNTO) and AN was synthesized by a solvent evaporation method [564]. The formation of co-crystals was confirmed by SEM, powder XRD, IR, and Raman spectroscopies. Compared to pure HNTO and AN, the co-crystals crystallized into a new polymorphic form and exhibited a reduced sensitivity to friction and impact. The DSC analysis showed the complete absence of all temperature-dependent phases of AN in the new co-crystal. This material can be used as a potential oxidizer for composite solid propellant formulations.

Table 39: Properties of NTO salts of nitrogen-containing inorganic and organic bases.

### Alkylamine Salts of NTO

The crystal structure of the ethylenediammonium salt (ENTO) of 3-nitro-1,2,4-triazol-5-one,  $(\text{CH}_2\text{NH}_3)_2 \bullet 2\text{C}_2\text{N}_4\text{O}_3\text{H}$ ,  $M = 320.22 \text{ g/mol}$ , was determined by XRD [565]. The crystals are triclinic, space group  $P\bar{1}$ , with unit cell parameters of  $a = 6.528 \text{ \AA}$ ,  $b = 10.780 \text{ \AA}$ ,  $c = 14.236(3) \text{ \AA}$ ,  $\alpha = 81.11^\circ$ ,  $\beta = 87.13^\circ$ ,  $\gamma = 74.05^\circ$ ,  $V = 951.73 \text{ \AA}^3$ ,  $Z = 3$ , and  $\rho = 1.676 \text{ g/cm}^3$ . There are 1.5 formula units in the asymmetric unit.

The thermal stability of 15 ring-substituted arylammonium salts of NTO was studied by dynamic and isothermal TGA, DTA, and explosion delay measurements [566]. Some of the salts were found to dissociate and liberate amine by N–H bond heterolysis prior to explosion, whereas in other cases, the amine part was not liberated. However, the evolution of  $\text{NO}_2$  seemed to accelerate explosions. When heated in air, the oxidation-reduction reactions near the surface of thermolyzing materials may be responsible for the decomposition of these salts prior to explosion.

The dimethylammonium salt of NTO  $[(\text{CH}_3)_2\text{NH}_2^+][\text{C}_2\text{N}_4\text{O}_3\text{H}^-]$  was prepared by mixing 3-nitro-1,2,4 triazol-5-one (NTO) ethanol solution and dimethylamine aqueous solution [567]. Single crystals suitable for XRD measurement were obtained by recrystallization from the mixed solvents of dimethyl formamide and methanol at room temperature. The crystal is monoclinic, space group  $P2_1/c$ , with crystal parameters of  $a = 0.7116(1) \text{ nm}$ ,  $b = 0.8735(2) \text{ nm}$ ,  $c = 1.3160(3) \text{ nm}$ ,  $\beta = 101.12(2)^\circ$ ,  $V = 0.8026(3) \text{ nm}^3$ ,  $\rho_c = 1.450 \text{ g/cm}^3$ , and  $Z = 4$ . A theoretical investigation of  $[(\text{CH}_3)_2\text{NH}_2^+][\text{C}_2\text{N}_4\text{O}_3\text{H}^-]$  as a structure unit was carried out by quantum mechanical methods. The atomic net charge distribution and electron population analysis were calculated.

The dimethylamine salt of 3-nitro-1,2,4-triazol-5-one,  $[(\text{CH}_3)_2\text{NH}_2^+][\text{C}_2\text{N}_4\text{O}_3\text{H}^-]$ , can be prepared by simply mixing NTO ethanol solutions and dimethylamine aqueous solutions [568]. Single crystals suitable for XRD measurement were obtained by recrystallization with the mixed solvent of methanol and dimethyl formamide ( $v/v = 5:1$ ) at room temperature. The crystals were monoclinic, space group  $P2_1/c$ , with crystal unit cell parameters of  $a = 0.7116(1) \text{ nm}$ ,  $b = 0.8735(2) \text{ nm}$ ,  $c = 1.3160(3) \text{ nm}$ ,  $\beta = 101.12(2)^\circ$ ,  $V = 0.8026(3) \text{ nm}^3$ ,  $\rho_{\text{calc}} = 1.450 \text{ g/cm}^3$ , and  $Z = 4$ . The melting enthalpy ( $\Delta H_m$ ) and melting entropy ( $\Delta S_m$ ) of dimethylamine salt of 3-nitro-1,2,4-triazol-5-one were  $14.94 \pm 0.51 \text{ kJ/mol}$  and  $32.37 \text{ J K}^{-1} \text{ mol}^{-1}$ , respectively. The apparent activation energy and the pre-exponential constants of the exothermic decomposition reactions were  $109.84 \text{ kJ/mol}$  and  $10^{9.41} \text{ s}^{-1}$ , respectively.

The heat capacity of the dimethylamine salt of 3-nitro-1,2,4-triazole-5-one (DMANTO) was determined by a continuous  $C_p$  mode with a microcalorimeter [569]. The heat capacity of DMANTO as a function of temperature is

$$C_p = 2.8884 \times 10^2 + 3.2774T$$

where  $C_p$  is the molar heat capacity in  $\text{J kg}^{-1} \text{ K}^{-1}$  and  $T$  is the temperature in kelvin. The relationships between specific heat capacity and thermodynamic functions, enthalpy, entropy, and Gibbs free-energy of DMANTO in the range from 283 to 353 K (which is relative to the standard temperature of 298.15 K) were calculated. Using the relationship

between  $C_p$  and  $T$  and the thermal decomposition parameters, the adiabatic time-to-explosion of DMANTO was predicted to be between 13.45 and 13.67 s.

Four amine salts of 3-nitro-1,2,4-triazol-5-one (NTO) were prepared from inexpensive raw materials [570]. The ethylenediamine, hydrazinium, and ammonium salts of NTO were synthesized by mixing a solution of NTO with ethylenediamine, hydrazine hydrate, or ammonium carbonate, respectively. The hydroxylammonium salt of NTO was prepared in two steps by first reacting an aqueous solution of NTO with NaOH, then with hydroxylammonium chloride. The crystals were recrystallized from water/ethanol solutions. The structures of compounds were confirmed by IR,  $^{13}\text{C}$  NMR, and elemental analyses. The thermal stabilities of the four amine salts of NTO were studied by DSC-TG, VST, and a thermal explosion test. The thermal stability of the ethylenediamine salt was superior to hydroxylammonium salt and hydrazine salt, while the stability of the ammonium was the most inferior.

### Guanidine and Guanidine Derivative Salts of NTO

The properties of many salts of NTO with guanidine and aminoguanidines have already been listed in Table 33. The diaminoguanidinium salt of 3-nitro-1,2,4-triazol-5-one,  $M = 219.16$  g/mol, was prepared via an ion exchange method and crystallized from the aqueous solution [571]. The crystals were triclinic, space group  $P\bar{1}$ , with unit cell parameters of  $a = 6.735(2)$  Å,  $b = 6.753(2)$  Å,  $c = 9.844(2)$  Å,  $\alpha = 88.29(2)^\circ$ ,  $\beta = 77.17(2)^\circ$ ,  $\gamma = 86.50(2)^\circ$ ,  $V = 435.7$  Å<sup>3</sup>,  $Z = 2$ , and  $\rho_{\text{XRD}} = 1.671$  g/cm<sup>3</sup>.

The aminoguanidinium salt of NTO (AGNTO) was prepared by mixing aminocarbamide bicarbonate and 3-nitro-1,2,4-triazol-5-one [572]. The product was characterized by elemental analysis and IR spectra. The crystal structure of AGNTO was determined by single-crystal XRD. The crystal shape is monoclinic and belongs to space group  $P2_1/n$ . Crystallographic data are  $a = 0.67870(10)$  nm,  $b = 2.7915(4)$  nm,  $c = 1.2739(2)$  nm;  $\beta = 96.930(10)^\circ$ ,  $V = 2.3959(6)$  nm<sup>3</sup>,  $Z = 12$ , and  $\rho_c = 1.698$  g/cm<sup>3</sup>. This salt would be a very promising energetic material and it could be used as a constituent in gas-generating formulations.

The monohydrate of the salt formed by carbonylhydrazide with 3-nitro-1,2,4-triazol-5-one (NTO) was prepared by mixing aqueous solutions of carbonylhydrazide and NTO and crystallizing slowly from the concentrated solution [573]. The crystalline product was characterized by elemental analysis and IR spectroscopy. The crystal structure was determined by single-crystal XRD. The crystal shape is triclinic and belongs to space group  $P$ , with  $a = 6.639(1)$  Å,  $b = 11.481(1)$  Å,  $c = 13.692(2)$  Å,  $\alpha = 70.56(1)^\circ$ ,  $\beta = 88.19(1)^\circ$ ,  $\gamma = 77.03(1)^\circ$ ,  $V = 958(2)$  Å<sup>3</sup>,  $Z = 4$ , and  $\rho_c = 1.651$  g/cm<sup>3</sup>. This salt is an ionic compound composed of one carbonylhydrazide (CHZ) cation and one NTO anion.

The diaminoguanidinium salt of NTO (DAGNTO) was prepared by mixing NaNTO aqueous solutions and diaminoguanidinium chloride aqueous solutions [574]. Single crystals suitable for X-ray measurement were obtained by recrystallization from water at room temperature. The crystal shape is triclinic and belongs to space

group  $P\bar{I}$ , with crystal unit cell parameters of  $a = 0.6732(3)$  nm,  $b = 0.6745(3)$  nm,  $c = 0.9840(4)$  nm,  $\alpha = 88.309(7)^\circ$ ,  $\beta = 77.255(6)^\circ$ ,  $\gamma = 86.520(7)^\circ$ ,  $V = 4.349(3)$  nm<sup>3</sup>,  $Z = 2$ , and  $\rho_c = 1.674$  g/cm<sup>3</sup>. Theoretical investigations of DAGNTO as a structural unit were performed by MO quantum chemistry methods. The apparent activation energy and pre-exponential constant of the exothermic decomposition reaction of DAGNTO were predicted to be 112.15 kJ/mol and  $10^{9.603}$  s<sup>-1</sup>, respectively. The critical temperature of thermal explosion was predicted as 481.7 K (208.6 °C).

The guanidinium salt of 3-nitro-1,2,4-triazol-5-one (GNTO) was synthesized by the reaction of NaNTO and guanidinium chloride solutions in water at 333 K (60 °C) [575]. The thermal stability and non-isothermal decomposition kinetics of GNTO were examined by DSC and TGA/DTG. The kinetic equation governing the decomposition of GNTO is

$$\frac{da}{dT} = 10^{23.71} (1-a)^{\frac{2}{3}} \left[ 1 - (1-a)^{\frac{1}{3}} \right]^{\frac{1}{2}} \exp(-2.602 \times 10^5 / RT).$$

The critical temperature of thermal explosion was predicted as 529.44 K (256.29 °C). The specific heat of GNTO was determined using a micro-DSC method and the standard molar specific heat capacity was 236.88 J mol<sup>-1</sup> K<sup>-1</sup> at 298.15 K. The calculations predicted an adiabatic time-to-explosion of GNTO as 102 s.

The guanilylurea salt of 3-nitro-1,2,4-triazol-5-one (GUNTO) was synthesized from guanilylurea hydrochloride and NTO as starting materials with total yields of over 85% [576]. Its structure was characterized by IR, NMR, MS, elemental analysis, and XRD. Calculation results showed that with a real density of 1.72 g/cm<sup>3</sup> and a calculated enthalpy of formation of -347.35 kJ/mol, the theoretical detonation velocity and detonation pressure predicted by the Kamlet formulas were 6683 m/s and 19.27 GPa, respectively. The material was insensitive to impact and friction and the drop height of impact sensitivity H50 was more than 125.8 cm. The exotherm peak temperature of the DSC thermogram at a heating rate of 10 °/min was 509.9 K (236.8 °C). In comparison with other amine salts of NTO, GUNTO has higher nitrogen content, better thermal stability, and lower sensitivity.

### Heterocyclic Amine Salts of NTO

3-Nitro-1,2,4-triazole-5-one forms energetic salts with several organic, nitrogen-rich bases. Many energetic salts composed strictly of azolium cations and azolate anions (e.g., 3-nitro-1,2,4-triazolate-5-one [NTO], 5-nitroimino-tetrazolate, 3-nitro-5-trifluoromethyl-1,2,4-triazolate, 3,5-dinitro-1,2,4-triazolate, 4,5-dinitro-imidazolate, 3,5-dinitro-pyrazolate, and 5-nitro-tetrazolate) were synthesized and characterized [577]. Most of the salts exhibited good physical properties, which include relatively high densities (1.38–1.75 g/cm<sup>3</sup>), high positive HOFs, and moderate detonation properties. Properties of the salts derived from heterocyclic amines with NTO and several other nitrotriazoles and nitrotetrazole are summarized in Table 40.

Table 40: Properties of salts derived from heterocyclic amines and nitroheterocyclic compounds.

| Compound name                                               | T <sub>m</sub> |     | T <sub>dec</sub> |     | D                 | OB   | N    | $\Delta H_f$ | P     | D    | I <sub>sp</sub> |

Data source: [577].

The crystals of the 3-amino-1,2,4-triazolium salt of 3-nitro-1,2,4-triazol-5-one, with  $M = 214.2 \text{ g/mol}$ , are monoclinic and belong to space group  $P2_1/c$ , with unit cell parameters of  $a = 6.539(2) \text{ \AA}$ ,  $b = 19.063(8) \text{ \AA}$ ,  $c = 6.749(4) \text{ \AA}$ ,  $\beta = 94.31^\circ$ ,  $V = 838.9(6) \text{ \AA}^3$ ,  $Z = 4$ ,  $\rho_{\text{pyc}} = 1.716 \text{ g/cm}^3$ , and  $\rho_{\text{XRD}} = 1.700 \text{ g/cm}^3$  [578]. The amine groups are planar with the five-membered ring of 1,2,4-triazole, the dihedral angles between cations and anions are  $172.9^\circ$ , and the nitro groups are rotated  $4.2^\circ$  out of the plane of the triazolone. The proton is linked, not at the amine group, but the 4-position of 3-ATA. The charge of the anions is mainly concentrated at the N4 atom of NTO. All H atoms except those on the C atom are involved in hydrogen bonds.

A salt from 3,3-dinitroazetidine (DNAZ) and 3-nitro-1,2,4-triazol-5-one (NTO) was prepared by mixing DNAZ and NTO in ethanol solutions [579]. Single crystals suitable for XRD measurement were obtained, which belong to monoclinic, space group  $P2_1/n$ , with unit cell parameters of  $a = 1.4970(4) \text{ nm}$ ,  $b = 0.6325(2) \text{ nm}$ ,  $c = 2.2347(7) \text{ nm}$ ,  $\beta = 96.55(1)^\circ$ ,  $V = 2.1022(11) \text{ nm}^3$ ,  $\rho_c = 1.752 \text{ g/cm}^3$ , and  $Z = 8$ . Based on the analysis of the molecule structure, a theoretical investigation of the title compound was carried out and a natural atomic charge and NBO analysis were performed. The thermal stability of DNAZ • NTO was measured by DSC and TGA/DTG, yielding the apparent activation energy ( $E_a$ ) and pre-exponential constant ( $A$ ) of the main exothermic decomposition reaction.

The thermal behavior of NTO-DNAZ was studied under a non-isothermal condition by DSC and TGA/DTG methods [580]. The kinetic parameters were obtained from the analysis of the DSC and TG/DTG curves using the Kissinger method, the Ozawa method, the differential method, and the integral method. The main exothermic decomposition reaction mechanism of NTO • DNAZ was classified as a chemical reaction. The kinetic parameters of the reaction were  $E_a = 149.68 \text{ kJ/mol}$  and  $A = 10^{15.81} \text{ s}^{-1}$ . The standard specific heat capacity of NTO • DNAZ was  $352.56 \text{ J mol}^{-1} \text{ K}^{-1}$  at  $298 \text{ K}$ .

The salts formed from *N,N*-dialkyl imidazole ( $\text{Cx-im}$ ,  $x = 3, 4, 5, 6$ ) for the cation and 3-nitro-1,2,4-triazole-5-one (NTO) for the anion have very low melting points and qualify as ionic liquids [581]. Their structures were identified by IR,  $^1\text{H}$  NMR, and elemental analysis. Their density, solubility, viscosity, and thermal properties were measured. The results showed that NTO-alkyl imidazolium ionic liquids dissolve in acetonitrile, dimethylformamide (DMF), dimethylsulfoxide (DMSO), and other organic solvents with a larger dielectric constant. Their density was greater than  $1.897 \text{ g/cm}^3$  and thermal transition temperatures of solid phase to liquid phase was less than  $238.7 \text{ K}$  ( $-34.4^\circ\text{C}$ ). The temperatures of 5% mass loss were about  $493 \text{ K}$  ( $220^\circ\text{C}$ ), having better thermal stability than some of the other EILs. A new ionic compound  $(3\text{-ATz})^+(\text{NTO})^-$  was synthesized by the reaction of 3-amino-1,2,4-triazole (3-ATz) with NTO in ethanol.

#### 8.14.3.4 Analysis Methods and Specifications of NTO

The assay of NTO can be determined by non-aqueous volumetric titration with a standardized solution of sodium methanolate in methanol [582]. The standard deviation was 0.16% after more than 20 repeated titrations on the same sample.

A silver nano-film was used as the surface-enhanced Raman spectroscopy (SERS) substrate for the analysis of NTO in aqueous solutions [583]. The detection limits of NTO in deionized (DI) water and aged tap water were 35 µg/L (0.35 ng) and 0.35 mg/L (3.5 ng), respectively. pH variation in the range of 4.7 to 9.1 did not affect the position of SERS NTO bands but affected the band intensity. The effect of eight common ions in natural waters on the SERS of 3.5 mg/L NTO was evaluated.  $K^+$ ,  $Na^+$ ,  $Ca^{2+}$ , and  $Mg^{2+}$  at 100 mg/L did not have a significant negative effect on the SERS of 3.5 mg/L NTO because NTO has a stronger affinity for the silver nano-film than the cations do. High chloride ion concentrations did interfere.

#### 8.14.3.5 Thermal Stability and Decomposition of NTO

##### Slow Thermal Decomposition of NTO

While information about the decomposition products of energetic materials is valuable for specifying the reaction pathways, kinetic constants are essential to describe burning or explosion processes. However, it is very difficult to acquire these data under such rapid phenomenon conditions. The rate of decomposition of NTO has been determined in the temperature range of slow, gradual thermal decomposition by IR spectroscopy, TGA, DTA [584], DSC [525], nitric oxide chemiluminescence [585], the analysis of the concentrations following partial decomposition in a sealed tube [586], and also with a study of isotope effects [587–590]. The rates obtained by these methods yielded activation energies ranging from  $E_a = 170$  to 502 kJ/mol ( $E_a = 40.7$  to 120 kcal/mol). However, when the value of  $E_a$  is plotted against its pre-exponential ( $\ln A$ ) counterpart, most of these pairs produce points that lie on or are close to a single line as shown for NTO and other explosives [591]. This coincidence is frequently referred to as the “kinetic compensation effect.” That is, an increase in  $E_a$  does not reduce the rate correspondingly because of an offsetting increase in the  $A$  factor. Consequently, widely scattered values of Arrhenius parameters for a heterogeneous global decomposition process may produce the same rate at a given temperature (i.e., they are isokinetic) but will predict very different rates. It is evident that considerable care must be exercised when determining and interpreting the kinetic constants for the decomposition of a volatile energetic compound such as NTO. In the unconfined state, the kinetic constants may be a mixture of the rates of sublimation and decomposition, the balance of which shifts with changes in the experimental conditions. With appropriate precautions, these two dominating processes may be separated and independently investigated. If a mathematical expression for the thermal decomposition rate of NTO is desired, then the kinetics which yield activation energies in the vicinity of 326–351 kJ/mol (78–87 kcal/mol)

rather than 188–217 kJ/mol (45–52 kcal/mol) should be used. However, there has been no consensus on the mechanism of thermolysis of NTO for a long period.

The thermal decomposition of NTO was studied using DSC, TGA-MS, and accelerating rate calorimetry (ARC) [592]. In the DSC, no endothermic phase transitions were observed on heating NTO through the temperature program. The DSC spectrum of NTO showed only one peak; a very strong exothermic peak at 508 K (235 °C). In the DTA, an exotherm was observed having an extrapolated onset temperature of 543 K (270 °C) and a broad shoulder beginning at 505 K (232 °C). The decomposition of NTO by TGA proceeded as a two-step reaction. In the TGA thermogram, the onset temperature for rapid decomposition occurred at 543 K (270 °C), 22 minutes into the run. The rate of mass loss was a maximum at 549 K (276 °C), at 23 minutes into the run. The residual solid (at 623 K = 350 °C) amounted to roughly 12% of the original NTO mass. An IR spectrophotometric examination of the residue showed that it was not 1,2,4-triazol-3-one. The gases that evolved during the TGA run (H<sub>2</sub>O, NO, CO<sub>2</sub>) were identified by mass spectroscopy as they were generated. In the ARC, the first exotherm had an onset temperature of 459 K (186 °C) and an adiabatic temperature rise (AT) of 1.6 °C. The associated pressure increase was 0.69 atm and the maximum self-heat rate occurred at 459 K (186 °C). The onset temperature for the second exotherm occurred at 481 K (208 °C). The rapid temperature increase occurred at 485 K (212 °C). As a result of this exotherm, AT was 18 °C and the pressure increase was 10 atm. The maximum self-heat rate was 282 °C/min and occurred at 496 K (223 °C). The chemical equation suggested for the overall net reaction was

It was found that the stability of NTO is sensitive to the thermal age of the sample when the sample was isothermally aged in the ARC bomblet at 458 K (185 °C) for 24 h. Kinetic analysis suggested an auto-catalytic decomposition mechanism.

Electron paramagnetic spectroscopy (EPR) and HPLC were used to examine the decomposition of plain NTO and deuterated NTO during the photochemical and thermochemical decomposition of NTO [590, 593]. Solutions monitored by EPR showed that the NTO nitro group abstracts hydrogen atoms from other species and/or acetone solvent, as evidenced by the observation of EPR spectra with NTO hydroxy nitroxide radicals. The HPLC global kinetic studies conducted between 498 and 518 K showed that the decomposition of NTO may occur by a solid-state autocatalytic reaction scheme for which initiation and propagation contribute to the observed kinetic behavior. The decompositions were found to have an average global activation energy of 368 kJ/mol (88.0 kcal/mol). A primary kinetic deuterium isotope effect of 1.67 (2.44 at 298 K) indicated that nitrogen-hydrogen bond cleavage plays a significant role in the loss of NTO or deuterated NTO.

Under linear temperature increase conditions, the mechanisms and the kinetic parameters of thermal decomposition of NTO and NTO salts of the type  $M(\text{NTO})_m \cdot n\text{H}_2\text{O}$  for  $M = \text{Cu}$ ,  $m = 2$ ,  $n = 4$ ;  $M = \text{Pb}$ ,  $\text{H}_3\text{NCH}_2\text{CH}_2\text{NH}_3$ ,  $m = 2$ ,  $n = 0$ ;  $M = \text{K}$ ,  $\text{NH}_4$ ,  $m = 1$ ,  $n = 1$ , were obtained by TGA, DSC, IR, and XRD [525]. The thermal decomposition processes of the salts were already discussed in other sections of this book.

The critical temperatures of thermal explosion for NTO and its ENTO, KNT0, copper salt (CuNTO), and lead salt (PbNTO) were obtained using the stationary theory of thermal explosion, the calculation formula of estimating the critical temperature of thermal explosion under non-isothermal DSC conditions, and the determination method for the critical temperature of the thermal explosion of small-scale solid explosives and its data treatment method [594, 595]. The results of the four methods were in general agreement with each other and the differences were within 5%. The results indicated that the heat-resistance of NTO and its salts and that of the common explosives (HMX, RDX, PETN, and tetryl) decreases in the order  $\text{HMX} > \text{NTO} > \text{ENTO} > \text{KNT0} > \text{RDX} > \text{PETN} > \text{tetryl} > \text{PbNTO} > \text{CuNTO}$ .

To analyze the thermal sensitivity of a high explosive, it is necessary to understand that the thermal sensitivity can be divided into at least three different regimes: **(1)** molecular sensitivity, **(2)** decomposition sensitivity, and **(3)** the sensitivity to starting a self-sustained reaction. All three regimes were examined as follows: the molecular sensitivity by mass spectroscopy, the thermal stability by DSC and chemiluminescence (CL), the thermal decomposition path by laser-induced mass spectrometry (LI-MS), and the sensitivity to a self-sustained reaction by a laser ignition method. The decomposition of NTO based on the mass spectra of NTO decomposition under the influence of electron impact (EI) 20 and 70 eV electrons and chemical ionization spectra was investigated [585, 596]. The large abundance of the molecular ion in these spectra showed that NTO is a more stable molecule than TNT or RDX. The data acquired for NTO was summarized as a proposed mass spectral fragmentation path. Laser ignition measurements showed a strong pressure dependence, which indicated a multiple-phase (condensed and gas phase) ignition mechanism. The laser ignition measurements also showed that the sensitivity to ignition of NTO is slightly higher than that of TNT. The results of the LI-MS method applied to NTO implied that the probable decomposition path is elimination of  $-\text{NO}_2$  followed by a breaking of the azole ring. The CL method was used for the determination of the activation energy and the frequency factor ( $E_a = 140 \text{ kJ/mol}$ ) and  $A_0 = 5 \times 10^6 \text{ s}^{-1}$  in the temperature interval 373–413 K (100–140 °C). CL data for RDX and TNT were acquired for comparison. The DSC spectrum of NTO showed only one peak; a very strong exothermic peak at 526 K (253 °C). The experimental work was complemented by some quantum mechanical calculations. These were conducted in an attempt to verify the initial steps in the decomposition path and to explain the high stability of NTO.

The early reaction chemistry of NTO induced by drop weight impact, shock, heat, and radiation has been investigated by XPS and chemical ionization mass spectrometry.

try (CIMS) to observe and identify the partial decomposition products in the damaged samples [597, 598]. Several reaction intermediates have been identified, the focus of the reaction being the single nitro group present on this molecule. XPS spectra indicated the loss of  $\text{NO}_2$  concentration in response to damage in all cases. Additional chemical states were suggested in the XPS nitrogen N(1s) spectrum by the appearance of a new peak at a binding energy below that of the triazole ring nitrogens. Mass spectrometry provided the molecularly specific information needed to identify molecular fragment species resulting from the decomposition reactions. Relative to the parent NTO molecule, mass peaks were observed that corresponded to the loss of one O atom, an NO fragment, and HONO formation.

To evaluate the hazards posed by NTO, its explosive properties were studied by differential thermal analyses and sensitivity tests [584]. NTO does not have very large exothermicity compared to ordinary explosives but it is classified as a self-reactive material that has shock initiation properties. Its impact sensitivity is not very high but the explosive strength is the same as that of TNT. The thermal decomposition of NTO proceeds according to the model of nucleus formation and growth, which states that germ nuclei grow linearly or two-dimensionally. The apparent activation energy is 219 kJ/mol.

The kinetics and mechanism of the thermal decomposition of NTO have been studied together with its morphology and evolved gaseous products using TGA, DTA, IR, DSC, XRD, and hot-stage microscopy [508]. The crystal belongs to the tetragonal system and has a  $c/a$  ratio of 0.329. The crystal structure unit cell parameters obtained from the XRD pattern were  $a = 20.000 \pm 0.005 \text{ \AA}$ ,  $b = 20.000 \pm 0.005 \text{ \AA}$ , and  $c = 6.573 \pm 0.005 \text{ \AA}$ . The kinetics of the thermolysis has been followed by both isothermal TGA and IR. The best linearity, with a correlation coefficient of 0.9937, was obtained for the Avrami-Erofeev equation,  $n = 3$ , in the range 0–83%  $\alpha$ , using isothermal TGA. A composite of three curves, the DTA, TGA, and DTG thermograms are shown in Figure 12. The TGA data indicated that NTO underwent decomposition in two steps; in the temperature range 524–535 K (251–262 °C) and then from 535 K (262 °C) onwards. The weight loss at the first stage was about 67%. The second stage is slower and results in about 23% mass loss. The DTA does not show any endotherms before the onset of the first exotherm, thus indicating that the compound decomposed without first melting. In DTA, the first exotherm was very sharp and occurred in the range 524–544 K (251–271 °C). The activation energy was found to be 186 kJ/mol, with  $\log(A)$  being  $16.64 \text{ s}^{-1}$ . The effect of a series of additives and metal oxides incorporated to an extent of 5% on the initial thermolysis of NTO has also been studied. Iron(III) oxide, copper(II) oxide, or magnesium oxide accelerated NTO decomposition. Evolved gas analysis (EGA) by IR showed that  $\text{CO}_2$ ,  $\text{NO}_2$ , NO, and  $\text{N}_2\text{O}$  were produced in larger amounts than CO and HCN. The cleavage of the C– $\text{NO}_2$  bond appears to be the primary step in the thermolysis of NTO.

Widely varied Arrhenius parameters have been published for the thermal decomposition of HMX, RDX, and NTO. Evaluation of these data revealed that an approxi-

**Figure 12:** TGA/DTA/DTG Thermograms of NTO decomposition. (Reprinted and modified from [508], with permission from ©1994 Elsevier; permission conveyed through RightsLink.)

mately linear relationship exists between  $\ln A$  and  $E_a$  for each compound, which is irrespective of the phase [591]. This kinetic compensation effect accounts for and unifies most of the differences in the reported rates. The range of data is qualitatively attributable to differences in the sample characteristics and experimental conditions. All  $E_a \dots \ln A$  sets lying on, or close to, the compensation regression line consistently account for the rate of thermal decomposition under the conditions reported.  $E_a \dots \ln A$  sets not lying on or near the compensation regression line represent a different process, or are incorrect. The kinetic compensation effect provides a rational method to select Arrhenius parameters and eliminate bad data to describe the global thermal decomposition rate of an energetic material.

The thermal decomposition of NTO and other energetic materials was examined by DSC and DTA/TGA [599]. The results are summarized in Table 41 and are illustrated in Figure 13.

**Table 41:** DSC and DTA/TGA of 3-nitro-1,2,4-triazol-5-one (NTO).

**Figure 13:** DSC and DTA/TGA results with NTO. (Reproduced and modified from [599].)

An exothermic extrapolated temperature of 542 K (268 °C) and a broad shoulder beginning at 505 K (232 °C) were observed (Figure 13). The residual solid (at 523 K = 350 °C) contained roughly 10% of the original NTO mass. This was in good agreement with [592]. The two stages in the TGA curve were caused by an impurity in the investigated NTO sample. Other analyses had shown that this particular sample was polluted with nitric acid and resulted in a low pH-value. Impurities can result in a different thermogram than would be obtained with a pure chemical substance.

NTO and many other triazole, tetrazole, triazine, tetrazine, furazan, and acyclic backbone compounds were shown by IR spectroscopy to convert to polymeric, melon-like, cyclic azine residues upon heating to  $T \geq 773$  K ( $\geq 500$  °C) [489, 490]. These compounds include NTO, 3-amino-5-nitro-1,2,4-triazole (ANTA), and nitroguanidine. The melon-like residue could suppress the burn rate of solid propellants because they have a high thermal resistance. In clarifying the pyrolysis mechanisms, the IR-active gaseous products from thermolysis were determined as a function of pressure and were related to the atom connectivity in the parent molecules from which they originated.

The thermal decomposition of NTO was examined over the temperature range 493–553 K (220–280 °C) using both neat NTO and NTO in aqueous and methanol solutions [586, 600]. The decomposition of NTO in the presence of TNT was also examined. Activation parameters were calculated for all thermolyses. The Arrhenius plot for NTO in the range 433–553 K (160–280 °C) gave an activation energy of 329 kJ/mol (78.6 kcal/mol) with a pre-exponential coefficient of  $2.53 \times 10^{29}$ . When mixtures of NTO and TNT were decomposed, the decomposition rate of both components was enhanced. Additives such as NO<sub>2</sub>, ammonia, nitric acid, and AN also accelerated the decomposition of NTO and TNT. Decomposition of deuterated NTO (neat and in solution) was noticeably slower than that of proteo-NTO, which is indicative of an intramolecular deuterium kinetic isotope effect. An intermolecular deuterium kinetic isotope effect (DKIE) was also observed when NTO was decomposed in deuterated solvent or a mixture with TNT-d(3). It was concluded that the rate-determining step in at least one NTO thermolysis pathway involved hydrogen transfer to the nitro group, followed by the subsequent loss of HONO. This mechanism is believed to be dominant at low temperatures, while at high temperatures C–NO<sub>2</sub> homolysis is probably a competitive decomposition pathway. It was concluded that TO, while formed in the decomposition of NTO, was not an intermediate in the principal NTO decomposition pathway. Furthermore, while it appeared that NTO and TO promoted TNT decomposition by the same mechanism, hydrogen transfer to a nitro group (the mode by which TNT enhanced the decomposition of the two triazolone rings) differed. The kinetics and products of the decomposition of eight other triazole-like rings were examined for comparison. Thermal stability was related to ring substitution; rings with NO<sub>2</sub> and NH<sub>2</sub> substituents decomposed more rapidly at 543 K (270 °C) than those with O or H

on carbon. Hydrogen transfer to the nitro group of NTO was supported by the observation that only rings substituted with either  $\text{NO}_2$  or  $\text{NH}_2$  exhibited an intermolecular deuterium kinetic isotope effect. For NTO, the DKIE at 543 K (270 °C) was  $r_{\text{H2O}}/r_{\text{D2O}} = 2.1$ .

Isotope labeling not only with deuterium on the two hydrogen atoms of NTO but also with  $^{15}\text{N}$  at the 1- and 2-positions. This was used to identify the weak links in the NTO molecule. The  $^{15}\text{N}$ —H coupling would provide unequivocal assignments for  $^1\text{H}$  and  $^{15}\text{N}$  NMR spectra and the acidic proton. The gas products HCN,  $^{15}\text{N}^{14}\text{N}$ ,  $^{15}\text{N}_2$ , and CO were detected by mass spectrometry [601, 602]. The products of thermal decomposition at 543 K (270 °C) were identified spectroscopically. NMR spectra revealed that thermal decomposition results in the formation of 2,4-dihydro-3H-1,2,4-triazol-3-one and ammonia (the latter was observed as ammonium ion). Solid and gaseous thermal decomposition products of NTO-1,2- $^{15}\text{N}$  were detected by NMR spectroscopy and mass spectrometry, respectively. For the first time, ammonia has been reported as a product. The production of ammonia as a thermal decomposition product from NTO was surprising and it was believed that the major counter anion is the conjugate base of NTO. The yield of ammonia varied from 5 to 10%. The yield of ammonium ion is probably limited by the availability of water for hydrolysis of the C—N group. A stepwise mechanism involving the homolysis of C—N bond followed by ring closure to form  $^{14}\text{N}$ — $^{15}\text{N}$  bond is the most probable mechanism.

The physical and chemical properties of the high explosive NTO have been investigated by IR spectroscopy and thin-film infrared laser pyrolysis to determine the initial chemical steps in the decomposition mechanism [141, 603]. It was found that the initial steps form carbon dioxide by a bimolecular reaction mechanism involving the reaction of two NTO molecules in the crystal. The relative insensitivity of NTO to accidental ignition is attributed to a unique crystal structure that holds reactive groups of the molecules apart from each other and forces disruption of the crystal structure (melting) before a reaction can take place. A similar mechanism has been found to explain the insensitivity of 2,4-dinitroimidazole compared with its structural isomer, 1,4-dinitroimidazole. It was found that NTO has a mechanism of thermal decomposition that is unique among high explosives. Whereas most explosives tend to react by loss of NO (or  $\text{HNO}_2$ ) in a unimolecular reaction, NTO has a bimolecular mechanism in which the nitro group of one molecule reacts with the carbonyl group of another NTO molecule, thereby forming  $\text{CO}_2$  as one of the initial products while still in the condensed phase. This mechanism may explain the low sensitivity of NTO to ignition by impact because the crystal structure is what keeps the groups separated and prevents ignition at temperatures lower than the melting point of NTO (535 K = 262 °C). The melting point is high because the NTO molecules form a hydrogen-bonded network which resists reorganization. It was suggested that the following characteristics may contribute to reducing the sensitivity of high explosives:

- a. bimolecular reaction mechanism (the rate depends on the local structure of the crystal)
- b. crystal structure that effectively separates reactive functional groups
- c. high melting point (preferably involving the formation of a hydrogen-bonded network)

Real-time surface analysis photoionization mass spectra of the shear-induced molecular-fragment emission from NTO were obtained by a surface analysis by laser ionization (SALI) apparatus [604]. Using vacuum UV single-photon ionization, the shear-induced NTO spectra were obtained with a spring-driven shearing device installed in a SALI chamber directly beneath the mass spectrometer sampling region. The shear-induced spectra were dominated by a peak at  $m/e$  99, which is not seen in the thermal or laser desorption spectra. This peak was assigned to the closed-shell triazole-diketone produced by a nitro-nitrite rearrangement and was followed by NO loss, then by rapid bimolecular H-atom removal. The stability of the cyclic diketone intermediate thus generated could help to explain the shock insensitivity of NTO. For comparison, spectra were obtained under either slow-heating or rapid pulsed-laser heating conditions. Laser-desorption spectra were also obtained, both on fresh NTO samples and samples that had been recovered from marginally sub-critical drop weight impact tests. Under the thermal or laser-desorption conditions, subsequent bimolecular H-atom removal to produce the closed-shell diketone was slower than unimolecular ring-opening adjacent to the carbonyl group. This sequence satisfactorily explains the following: **(1)** the initial formation of  $\text{CO}_2$  that has been previously reported, **(2)** the result of nitrogen double-labeling experiments, and **(3)** the fact that neither  $\text{NO}_2$  nor  $\text{HONO}$  have been seen as substantial initial products of NTO decomposition (at least not by this investigator).

Simultaneous STMBMS and TOF spectra have been developed to study reactions that occur during the thermal decomposition of energetic materials. The data obtained with these techniques are the identity of the reaction products and their rates of gas formation as a function of time. In the case of NTO, the pyrolysis of NTO resulted in the formation of gaseous products and a solid residue [485]. The identity of the major gaseous products and their origin from within the NTO molecules were determined based on the results from pyrolysis of isotope-labeled NTO,  $\text{NTO-3-}^{13}\text{C}$ ,  $\text{NTO-1,2-}^{15}\text{N}$ , and  $\text{NTO-}^2\text{H}$ . The identification of the products showed the major gaseous products to be  $\text{N}_2$ ,  $\text{CO}_2$ ,  $\text{NO}$ ,  $\text{HNCO}$ ,  $\text{H}_2\text{O}$ , and some  $\text{N}_2\text{O}$ ,  $\text{CO}$ ,  $\text{HCN}$ , and  $\text{NH}_3$ . The  $\text{N}_2$  was mostly derived from the N-1 and N-2 positions with some being from the N-4 and N-1 or N-2 positions. The  $\text{CO}_2$  was derived from both carbons in the NTO molecule in comparable amounts. The overall thermal decomposition of NTO in the temperature range evaluated between 463 and 523 K (190 and 250 °C) involved four major processes: **(1)** NTO sublimation; **(2)** an apparent solid-solid phase transition between 463 and 468 K (190 and 195 °C); **(3)** a decomposition regime induced by the presence of exogenous  $\text{H}_2\text{O}$  at

the onset of decomposition; and (4) a decomposition regime that occurs at the onset of decomposition and continues until the depletion of NTO.

The thermal decomposition of NTO was studied by many groups of investigators. Such interest was a result of the unusual decomposition behavior of NTO (the isomerization of the nitro group into the *aci*-form at high temperatures, which was followed by its decomposition). This circumstance resulted in two kinetic equations with vastly different activation energies that can be used to describe the decomposition of NTO in the solid state: in the low-temperature region,  $E_a = 172.0 \text{ kJ/mol}$  (41.1 kcal/mol), which is characteristic for the rupture of C–NO<sub>2</sub> bonds, and in the high-temperature region,  $E_a = 322\text{--}368 \text{ kJ/mol}$  (77–88 kcal/mol), a formal value connected with *aci*-isomer decomposition, the concentration of which increased with temperature. According to thermocouple-aided measurements and burning-rate studies, low values of heat flux from the gas phase at pressures up to at least 2 MPa allowed consideration of the condensed-phase chemistry as determining the combustion of NTO [484]. Rate constants of the dominant combustion reaction in the pressure range of 0.4–10 MPa have been obtained from the Zeldovich expression. The average specific heat was calculated to be  $1.46 \text{ kJ kg}^{-1} \text{ K}^{-1}$  ( $0.35 \text{ cal g}^{-1} \text{ K}^{-1}$ ) from experimental data on thermal diffusivity ( $1.7 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$ ). Strand density was  $1.74 \text{ g/cm}^3$  and thermal conductivity of the condensed phase was assumed to be  $5.1 \times 10^{-2} \text{ kJ s}^{-1} \text{ m}^{-1} \text{ K}^{-1}$  ( $0.00123 \text{ cal s}^{-1} \text{ cm}^{-1} \text{ }^\circ\text{C}^{-1}$ ). The heat of reaction,  $Q$ , was taken as  $1297 \text{ kJ/kg}$  (310 cal/g), and the heat of melting as  $215.5 \text{ kJ/kg}$  (51.5 cal/g). During combustion, NTO is in the molten state at the surface, having been isomerized into the *aci*-form. Therefore, the kinetics of NTO decomposition derived from the combustion model, for the temperature range 630–790 K,

$$k = 10^{13.91} \times \exp(-19420/T) \text{ s}^{-1},$$

differ from the kinetics of decomposition in solid. In other studies, decomposition of NTO has been studied in solutions at reduced temperatures. However, it is not obvious if isomerization proceeded to completion at those conditions. At the same time, it is well-known that many salts of nitro compounds contain the nitro group in the *aci*-form. Decomposition rate constants of a water solution of NTO were close to rate constants of the leading combustion reaction.

This very detailed and all-encompassing review deals with the chemistry and thermolysis of NTO and plausible decomposition pathways followed during the decomposition of NTO induced by X-rays, UV, laser, or photochemical irradiation. It is a good introduction to the decomposition of NTO [605]. For a long time, controversy existed among investigators regarding the decomposition mechanism of NTO. One school of thought suggested that the first step in the thermal decomposition of NTO is the scission of the C–NO<sub>2</sub> bond, either by direct thermal activation or catalyzed by H atom transfer and loss of HONO. The other school of thought maintained that the first decomposition products are CO<sub>2</sub> and N<sub>2</sub>O. Other workers have also reported CO<sub>2</sub> and N<sub>2</sub> as gaseous products while others detected NO<sub>2</sub> and HONO in small amounts or not at all. High-speed photographic studies of the impact responses of NTO may help to

explain processes during shock initiation of the material. The thermal decomposition kinetics of NTO can be explained by using isotope-labeled NTO. Before NTO can advance to widespread use as an explosive, analytical methods of detection, as well as methods for the safe disposal of NTO, need to be developed.

An examination of NTO decomposition by TGA and DSC showed that the heating of NTO leads to competitive sublimation and condensed-phase exothermic decomposition events [606]. Model-free isoconversional analysis provided activation energies ( $E_a$ ) for these processes as a function of the extent of conversion,  $\alpha$ . Sublimation occurs most readily in an open pan. More than simple sublimation was observed, with a global activation energy of  $E_a = 130\text{--}140\text{ kJ/mol}$  for sublimation. Non-isothermal TGA and DSC traces run on pierced pan samples provided convincing evidence for competitive sublimation and condensed-phase decomposition of NTO. Confining NTO samples in a closed pan resulted in condensed-phase decomposition that leads to the formation of gaseous reaction products and showed autocatalytic behavior during the latter stages. Isoconversional analysis of DSC traces of closed-pan samples yield activation energies for exothermic decomposition that increase from  $E_a = 273\text{ kJ/mol}$  for  $\alpha = 0.01$  to a plateau of  $333\text{ kJ/mol}$  for  $0.17 \leq \alpha \leq 0.35$  prior to decreasing to  $184\text{ kJ/mol}$  for  $\alpha = 0.99$ . The decrease in  $E_a$  with  $\alpha$  during the latter stages of decomposition agrees with previous reports of autocatalytic behavior.

The literature dealing with crystal structure, thermolysis, solubility, crystallization, and the applications of NTO, including the experimental and theoretical aspects of the crystal structure of various NTO salts, was thoroughly reviewed again in 2003 [480]. This is an update of a similar paper published by the same author(s) in 2001. At that time, the mechanisms of NTO decomposition and the reasons for its good thermal stability were still not quite understood. The theoretical considerations on the decomposition of NTO have been critically reviewed and new insights that were obtained from these works have been highlighted. The reported parameter sensitivity and performance of NTO available in the literature have been summarized.

The kinetics of the thermal decomposition of NTO in the temperature interval from 473 to 533 K (200 to 260 °C) were investigated using gas evolution pressure measured with a glass Bourdon gauge [607]. The overall decomposition reaction included two distinct stages: a fast first-order decomposition and a subsequent autocatalytic reaction. The contribution of the first stage increased with increasing decomposition temperature and decreasing loading density of the Bourdon gauge ( $m/V$ ). A period of preliminary heating at a lower temperature strongly influenced the autocatalytic stage when the decomposition was carried out at a higher temperature. In the temperature domain 473–479 K (200–220 °C), the Arrhenius constants of the decomposition reaction were found to be close to the values usually observed for nitro compounds:  $E_a = 173\text{ kJ/mol}$  and  $\log_{10} k \approx 12.5\text{ (s}^{-1}\text{)}$ . It was shown that a simple model of NTO decomposition based on an autocatalytic reaction of the  $n^{\text{th}}$  order can describe the course of the decomposition at high temperature but the  $n$  number appears to be excessively high, up to  $n = 4$ . A new model of the decomposition was developed, including an

initial monomolecular reaction, decomposition of the crystalline substance, and an autocatalytic reaction of NTO dissolved in liquid decomposition products. This model gave the common order of an autocatalytic reaction with  $n = 1$ .

The strand burning rates of NTO were investigated at a pressure interval of 0.1–40 MPa and the temperature distribution profile in the combustion wave of NTO was measured at pressures of 0.4–2.1 MPa [483, 608]. Based on burn rate and thermocouple measurement data, the rate constants of NTO decomposition in the molten layer at 643–698 K (370–425 °C) were derived from a condensed-phase combustion model

$$k = 1.14 \times 10^{14} \times \exp(-39000/RT) \text{ s}^{-1}$$

and NTO vapor pressure above the liquid phase

$$\ln P = -9914.4/T + 17.12$$

and solid phase

$$\ln P = -12984.4/T + 22.78$$

were calculated. Taking into account the vapor pressure data obtained, the decomposition of NTO in the gas phase at 513–523 K (240–250 °C) was studied. The decomposition rate constants in the gaseous phase were found to be comparable with rate constants in the solid state. Therefore, a partial decomposition in the gas cannot substantially increase the total rate. High values of the activation energy for the solid-state decomposition of NTO are not likely to be connected with the sub-melting effect. This is because decomposition already occurs at temperatures well below the melting point. It has been suggested that abnormally high activation energy at the interval of 503–543 K (230–270 °C) must be attributed to the peculiarities of the NTO transitional process rather than strong bonds in the molecule. During decomposition, the NTO molecule may undergo isomerization into the *aci*-form, followed by C3–N2 heterocyclic bond rupture, resulting in the abnormally high value of the observed activation energy.

NTO is an insensitive molecule in comparison to general explosives and the NTO-based PBXs have a low vulnerability. The thermal decomposition characteristics of NTO and CL-20 were studied using TGA and DSC. The compatibility of the two explosives with silicone rubber used in PBX formulations, the decomposition kinetic parameters such as activation energies of decomposition, and the frequency factor of the decomposition reaction were evaluated by using non-isothermal DSC techniques [609]. Some of the results are shown in Table 42. The NTO/silicone combination was slightly less stable than NTO by itself.

In the NTO curves, no endothermic peak was demonstrated at the lower temperature region before decomposition but it accomplished a sharp exothermic peak from 547 to 561 K (274 to 288 °C) with a 5 to 30 °C/min. heating rate. The onset temperatures were 538, 543, 548, and 551 K (265, 270, 275, and 278 °C) for heating rates of 5, 10, 20, and 30 °C/min., respectively.

**Table 42:** Kinetic parameters of thermal decomposition of thermally resistant explosives.

| Explosive      | $E_a$                    | $\gamma_b^a$ | A                     | Temperature |         |

Data source: [609].

Thermal stability and decomposition kinetics for NTO were investigated by DSC and thermogravimetric-DTA (TGA-DTA) to obtain information on safety for handling, storage, and use [610]. The results of TGA analysis revealed that NTO decomposes completely in the temperature range of 523–573 K (250–300 °C). NTO is thermally stable until its decomposition. The decomposition kinetics of NTO were then studied by non-isothermal DSC under various heating rates. Kinetic parameters such as activation energy and the frequency factor for the thermal decomposition of energetic compounds were obtained via the methods proposed by ASTM E696 and Starink [611]. Other thermodynamic parameters which correspond to the activation of thermal decomposition and critical ignition temperatures of the compounds were also obtained.

DSC was used to study the catalytic effect of TAG-transition metal complexes (with or without the addition of graphene oxide) on the thermal decomposition of NTO [612]. The apparent activation energy of NTO decomposition was reduced by more than 180 kJ/g.

### Rapid Thermal Decomposition of NTO

Subsequent to studies of the slow decomposition of NTO, the objective of additional work was to determine the decomposition characteristics of NTO under combustion-like conditions by rapidly heated T-jump/FTIR spectroscopy [490, 613]. Discrepancies in the published global kinetic data for the thermal decomposition of NTO were shown to result partly from the inadequate consideration of the competing processes of sublimation and thermal decomposition. These processes were isolated and their kinetics determined separately. For sublimation,  $E_a = 107.9$  kJ/mol (25.8 kcal/mol),  $\ln(A, s^{-1}) = 29.2$  (isothermal at 0.002 atm);  $E_a = 119.7$  kJ/mol = 28.6 kcal/mol,  $\ln(A, s^{-1}) = 31.3$  (non-isothermal at 0.002 atm). The decomposition kinetics on semi-confined NTO (20 atm Ar pressure) determined by T-jump/FTIR spectroscopy yielded  $E_a = 364$  kJ/mol = 87.1 kcal/mol and  $\ln(A, s^{-1}) =$

74.8. From these and reported data, the kinetic constants for decomposition alone are  $E_a = 326\text{--}364\text{ kJ/mol}$  ( $78\text{--}87\text{ kcal/mol}$ ) and  $\ln(A, \text{s}^{-1}) = 67\text{--}78$ . Lower values of the Arrhenius parameters result predominately or partly from sublimation. An evaluation was made of whether T-jump/FTIR spectroscopy could determine the decomposition kinetics  $E_a$  and  $\ln A$  and thermochemical  $\Delta H_{\text{rm}}$  constants of an energetic material at high temperature and high heating rate.

A primary DKIE has been detected, suggesting that the N—H (or N—D) bond cleaves in the rate-determining step of NTO thermal decomposition. In another study, a DKIE and 1,2,4-triazol-3-one (TO) as a decomposition product were observed. TO itself does not exhibit a DKIE, suggesting that  $\text{—NO}_2$  of NTO accepts the transferred hydrogen followed by  $\text{C—NO}_2\text{H}$  cleavage. Similarly,  $\text{C—NO}_2$  bond homolysis leading to  $\text{NO}_2$  (or HONO) has been proposed to be the initial degradation reaction by laser-induced MS and Secondary Ion Mass Spectrometry (SI-MS), although very little  $\text{NO}_2$  was detected.

The pressure dependence of the relative concentrations of the initially detected IR-active gaseous products from NTO heated at  $300\text{ K/s}$  to  $723\text{ K}$  in Ar was determined in another study [489]. Below  $1\text{ atm}$ , NO dominated. However, between  $5$  and  $68\text{ atm}$ ,  $\text{CO}_2$  was the major decomposition product. The rationalization of this is that, at higher pressures, gaseous products are forced to remain in contact longer with the residue and the hot zone, which enhances secondary reactions and produces more stable products. Absorbances indicative of NO appeared after several minutes. No HONO was detected. Another study remarkably revealed ammonia (detected as ammonium ion) in addition to TO as decomposition products by NMR. In summary, three studies proposed that  $\text{C—NO}_2$  homolysis is a major reaction, but a large amount of  $\text{NO}_2$  was reported in only one of these studies. A fourth study theorized that  $\text{NO}_2$  formed as a secondary product from the oxidation of NO. The oxidant was not identified. Cleavage of the N—H bond was proposed by many to be the rate-determining step.  $\text{CO}_2$  was detected as the initial product by rapid laser heating and as the major product by rapid thermolysis at pressures greater than  $5\text{ atm}$  (see also [524, 525]).

Films of NTO transiently heated by a pulsed laser showed only CO as the initial reaction product; there was no evidence of NO or HONO. Thin films of NTO were subjected to rapid pyrolysis using a pulsed IR laser to determine the initial steps of thermal decomposition under conditions of rapid heating [614]. After heating, the film was quenched to  $77\text{ K}$  in about  $2\text{ ms}$ , thereby trapping reaction products, which were subsequently detected by transmission FTIR. The first observed product of the decomposition was  $\text{CO}_2$ . No evidence was found for the formation of  $\text{NO}_2$  or HONO in the early stages of thermal decomposition. The experimental results showed that the  $\text{CO}_2$  reaction product was formed by bimolecular oxygenation of the carbonyl group by the nitro group of an adjacent NTO molecule. This conclusion differed from mechanisms proposed by other investigators based on their slow heating experiments.

### 8.14.3.6 Computational Chemistry of NTO Decomposition Reactions

An *ab initio* quantum mechanical study of the energetics associated with several proposed initiation routes of NTO looked at geometries for all stationary points that were computed using restricted Hartree-Fock self-consistent field (HF SCF) analytical gradient methods [615]. The theoretical harmonic vibrational frequencies for NTO were scaled by a factor of 0.91 to account for the effects of anharmonicity and electron correlation. Their theoretical gas phase values for the bond lengths compared well with those of experimental values, except one for the C5–N1 bond. Harmonic vibrational frequencies were computed to characterize the species at the stationary points. The previously reported mechanisms examined included decomposition initiated by C–NO<sub>2</sub> homolysis, migration of ring substituents and ring-opening processes. Based on the energetics of the various schemes, the results of the computations suggested that C–NO<sub>2</sub> bond homolysis is the most probable initial step for the unimolecular decomposition of NTO.

In modeling the thermal decomposition kinetics of NTO, including 39 decomposition paths among 18 intermediates and 14 transition states, three types of intra-molecular proton migration and the direct scission of the C–NO<sub>2</sub> bond were regarded as the initial steps of the unimolecular decomposition of NTO [616]. The activation energies of the radicalization C–NO<sub>2</sub> homolysis step were calculated as 331.2, 333.8, and 337.4 kJ/mol (79.158, 79.781, and 80.652 kcal/mol) for the three types of proton migration. The activation energies of the ionization C–NO<sub>2</sub> scission step were 1098, 1101, and 1139 kJ/mol (262.488, 263.138, and 272.278 kcal/mol) for the three types of proton migration. The bottle-neck activation energies of the C–NO<sub>2</sub>H cleavage were 229.8, 264.7, and 298.1 kJ/mol (54.936, 63.257, and 71.247 kcal/mol). Two of the paths have the smallest bottle-neck activation energy. Both have two proton migration steps and one internal rotation step before C–NO<sub>2</sub>H cleavage. At lower temperatures, vibrational energy accumulated slowly. When the energy is high enough and the reaction time is long enough for structure transformation, these two mechanisms should be the most probable decomposition paths. At high temperatures, the shortest (four steps) mechanism which goes through radicalization C–NO<sub>2</sub> scission, should be the dominant path. There were five tautomers found in this study. Four of them are intra-molecular proton migration tautomers. The other one is an internal rotational tautomer. Their energy barriers for structure transfer are lower than any of the activation energies of the decomposition reactions, which makes them more likely as intermediates. This may be regarded as one explanation of the insensitive properties of NTO.

The 5-nitro-2,4-dihydro-3H-1,2,4-triazol-3-one dimer reaction path leading to CO<sub>2</sub> in the gas phase was calculated by a DFT method [497]. *Ab initio* DFT calculations were used to study the structures and energies of the reactants, products, intermediate products, and transition states for the dimer reaction mechanism. It was found that there is a reaction path for the production of CO<sub>2</sub> through the dimer reaction with a potential energy barrier of 367 kJ/mol (87.8 kcal/mol). This study has revealed a series of NTO dimer reaction paths through four intermediates and five transition states with

the evolution of nitroso-TO, CO<sub>2</sub>, N<sub>2</sub>, HONO, and HCN, in that order. This seems to suggest that CO<sub>2</sub> is produced through a cluster of NTO molecules in the gas phase.

DFT calculations with dispersion-correction (DFT-DC) were used to study the effects of crystal lattice vacancies and pressure on the structure and initial decomposition of crystalline β-NTO [617]. A comparative analysis of the chemical behaviors of NTO in the ideal bulk crystal and vacancy-containing crystals under applied hydrostatic compression was considered. Calculations of formation energy, vacancy interaction energy, electron density difference, and frontier orbitals revealed that the stability of NTO can be effectively manipulated by changing the molecular environment. Bimolecular hydrogen transfer was suggested to be a potential initial chemical reaction in the vacancy-containing NTO solid at 50 GPa. This would take place before the C–NO<sub>2</sub> bond dissociation as a step that initiates its decomposition in the gas phase. The vacancy defects introduced into the ideal bulk NTO crystal can produce a localized site, where the initiation decomposition is preferentially accelerated and then promotes further decompositions.

#### 8.14.3.7 Photolysis of NTO

During UV photolysis, NTO abstracts hydrogen from the solvent or from other NTO molecules and forms a free radical: hydroxy-4-oxo-2,3,4-triazolyl nitroxide [590, 593]. The free radicals can be identified by electron spin resonance. If NTO is photolyzed in an alkaline solution with nitromethane, the nitromethane *aci* anion acts as a spin trapping agent, forming an NTO ring-intact anion free radical rather than a simple radical adduct [618]. The free radical is the product of electron transfer between *aci*-nitromethane and NTO. Its EPR signal consisted of a triplet of quartets. The photolysis of NTO in alkaline solutions is a candidate method for the disposal of NTO and the clean-up of NTO production waste waters.

The initial decomposition products of NTO were characterized using laser-induced decomposition of a solid sample [619]. The heating of solid NTO samples was achieved by irradiation with 7 ns pulses of 266 nm laser light while the gas-phase products were detected using 118 nm single-photon ionization in a TOF mass spectrometer. Product translational temperatures and relative product yields were obtained by analysis of time-of-arrival scans. The translational temperature depended linearly on the decomposition laser fluence and agreed with the results of a calculation of the temperature rise in the irradiated volume using a heat conduction equation. The relative product yields were used to determine the percentage decomposition of NTO as a function of temperature. The temperature dependence of the experimental fractional decomposition was consistent with that obtained from calculations of the temperature dependence of NTO unimolecular decomposition. The temperature dependence of the relative product yields was used to identify the initial channels. The initial reaction appeared to be bimolecular with a net loss of an O atom to yield nitroso-TO. Early unimolecular reactions included the loss of NO<sub>2</sub> and the nitro-nitrite rearrangement followed by a loss of NO.

Waste water from NTO production facilities may contain residual NTO that cannot be released to surface waters. A remediation method based on photochemical decomposition and Fenton oxidation of NTO has been evaluated by monitoring the mineralization of  $^{14}\text{C}$ -labeled NTO [620]. The  $\text{TiO}_2$ -catalyzed photodegradation ( $\lambda > 290\text{ nm}$ ,  $\text{TiO}_2$  0.4 g/L, NTO 150 mg/L) leads to the complete mineralization of NTO in 3 h. This degradation involves a simultaneous denitrification and ring scission of NTO, leading to nitrites, nitrates, and carbon dioxide. No significant photo-degradation of NTO was detected in the absence of the catalyst. Long-term irradiation over one week leads to complete degradation of concentrated NTO (5 g/L), suggesting that this method could be useful to clean up NTO wastes. Fenton oxidation offers an efficient cost-effective method for NTO remediation. This reaction is faster than the  $\text{TiO}_2$ -catalyzed photolysis and may find application in the mineralization of high concentrations of NTO (15 g/L). Fenton oxidation provokes ring cleavage and the subsequent elimination of the two carbon atoms of NTO as  $\text{CO}_2$ . During this reaction, the nitro group is completely transformed into nitrates.

#### 8.14.3.8 Radiolysis of NTO

NTO, RDX, HMX, and TATB were subjected to X-ray and UV radiation, and XPS was used to detect radiation-induced chemical changes [621]. In the group of four explosives, RDX was the most sensitive molecule to both the X-ray and UV radiation while HMX was only slightly less sensitive. NTO was found to be 1.5–3.0 times more sensitive to X-ray and UV damages than TATB. Radiation sensitivity decreased in the sequence  $\text{RDX} > \text{HMX} \gg \text{NTO} > \text{TATB}$ . The identification of decomposition products by chemical methods was consistent with the observed XPS data. XPS analysis of the X-ray-damaged residue suggested three decomposition products resulting from the loss of nitro, the reduction of nitro to nitroso, and the loss of NO. The direct loss of  $\text{NO}_2$  to produce 1,2,4-triazol-5-one is one possible mode of decomposition of NTO. Another product could be urazole resulting from the elimination of NO via a cyclic intermediate reduction of nitro to nitroso; this is also a possible decomposition mechanism as observed in RDX. It appears unlikely that the presence of decomposition products in damaged NTO will increase the sensitivity. Thus, it seems that NTO is unique among commonly used energetic materials in that it may not be sensitized by molecular degradation.

#### 8.14.4 Strand Burning of NTO

During strand burning of pressed pellets of NTO, burning does not transition into an explosion, as already discussed in this publication [622] (see also [483, 608]). NTO in the form of samples pressed into polymethylmethacrylate (PMMA) tubes of 7 mm diameter starts burning at 0.4 MPa at a rate of 0.3 mm/s. At atmospheric pressure, NTO can sustain combustion only when external heating is continuously provided by an electrically heated Nichrome wire. In doing so, a decomposition reaction with

the formation of gaseous products occurs but no gas-phase flame is observed. The gas flame appears at pressures when NTO is capable of sustained combustion. However, again, the burning is accompanied by the formation of copious yellow smoke and solid residue inside the tubes. The NTO burning rate-pressure dependence can be expressed as

$$r_b = 0.727p^{0.976}$$

for the pressure interval of 0.4–11.9 MPa, and

$$r_b = 1.56p^{0.667}$$

for the interval of 11.9–40 MPa, where  $r_b$  is the burning rate in mm/s and  $p$  is the pressure in MPa. The burning rates of NTO are close to the burning rates of TNT. As compared with HMX, NTO burns three times slower within the whole pressure interval.

#### 8.14.5 Explosive Performance of NTO

NTO has a calculated detonation velocity and pressure equivalent to that of RDX. Results from initial small-scale sensitivity tests indicated that NTO is less sensitive than RDX and HMX in all respects. A 4.13-cm-diameter unconfined plate-dent test at 92% of crystal density produced the detonation pressure predicted for NTO using Becker-Kistiakowsky-Wilson (equation of state, BKW) calculations [440, 441].

Measurements of detonation velocity of confined 12.7 mm charges pressed to 89.61 and 89.76% theoretical density, and a 15.9 mm charge pressed to 88.65% theoretical density gave scattered results. The detonation velocity for the 12.7 mm charges was relatively low at about 6000 m/s. The 15.9 mm charge gave a detonation velocity of 7440 m/s with a standard deviation of  $\pm 125$  m/s, thus indicating that stable detonation had been achieved [458]. Standard literature reference sources [62] list the detonation velocity, unconfined, as 7860 m/s at  $\rho = 1.80$  g/cm<sup>3</sup> and confined 7940 m/s at  $\rho = 1.77$  g/cm<sup>3</sup>, respectively.

#### 8.14.6 Critical Diameter of NTO Detonation

Tests on 12.7 mm diameter NTO samples showed that detonation can be achieved at this diameter at 91.0% theoretical density [458]. However, Lee and Coburn [440] also observed failure at 94.5% theoretical density for 12.7 mm diameter samples. NTO is not cap-sensitive. It will not detonate directly from an exploding bridgewire detonator (EBW) but requires a booster, which is typically RDX or PETN. The critical diameter of NTO may be close to 12.7 mm at 90% theoretical density, especially since detonations observed on confined charges at 12.7 mm diameter indicated potential instability. A provisional estimate for the unconfined critical diameter is  $11 \pm 2$  mm at 90% theoretical density.

### 8.14.7 Explosive and Safety Hazards of NTO

One of the many applications of NTO is as a replacement for RDX. Table 43 is a comparison of physical and sensitivity properties of NTO and RDX:

**Table 43:** Physical and explosive properties of NTO and RDX.

| Property                             | NTO                    |                        | RDX                    |                         |
|--------------------------------------|------------------------|------------------------|------------------------|-------------------------|
|                                      | SI units               | Other units            | SI units               | Other units             |
| Crystal density                      | 1930 kg/m <sup>3</sup> | 1.93 g/cm <sup>3</sup> | 1806 kg/m <sup>3</sup> | 1.806 g/cm <sup>3</sup> |
| DTA onset of exotherm                | >509 K                 | >236 °C                | 483 K                  | 210 °C                  |
| Enthalpy of formation                | −100.7 kJ/mol          | −14.30 kcal/mol        | +61.5 kJ/mol           | +14.71 kcal/mol         |
| Henkin critical temp. (0.64 mm size) | 510 K                  | 237 °C                 | 492.7 K                | 219.6 °C                |
| Impact sensitivity Type 12 tool      | 291 cm                 | —                      | 22 cm                  | —                       |
| Impact sensitivity Type 12B tool     | 293 cm                 | —                      | 41 cm                  | —                       |
| Spark sensitivity, 3 mil gap         | 0.91 J                 | —                      | 0.22 J                 | —                       |
| Spark sensitivity, 10 mil gap        | 3.40 J                 | —                      | 0.55 J                 | —                       |
| Vacuum stability, 48 h at 100 °C     | 0.2 mL/g               | —                      | —                      | —                       |
| Vacuum stability, 48 h at 120 °C     | 0.3 mL/g               | —                      | 0.12–0.9 mL/g          | —                       |

Data source: [440].

#### 8.14.7.1 Impact Sensitivity of NTO

In many instances, the properties of NTO were compared to those of RDX (the explosive it was often intended to replace) and to those of TNAZ and CL-20 (2,4,6,8,10,12-hexanitro-2,4,6,8,10,12-hexaazaisowurtzitane, HNIW) (explosives evolving at about the same time). A high-speed photographic study has been performed on the initiation mechanisms of CL-20 and NTO by drop-weight impact [623]. CL-20 was found to be slightly more sensitive and NTO less sensitive than  $\beta$ -HMX in a drop-weight test apparatus. NTO was found to be sensitized by both hard high-melting-point grits (60  $\mu$ m borosilicate or Pyrex glass) and brittle polymers. The heat-sensitive film was used to confirm that the events seen using high-speed photography were indeed deflagrations. In the BAM Drop Weight Impact Sensitivity Test Apparatus, the impact sensitivity of NTO was  $\geq 120$  Nm [62].

#### 8.14.7.2 Friction Sensitivity of NTO

In the BAM friction sensitivity test apparatus, the friction sensitivity of NTO was found to have the status of “no reaction” at the maximum pistil load of 353 N [62].

### 8.14.7.3 Auto-Detonation Sensitivity of NTO

The critical temperatures of thermal explosion for NTO were obtained using the stationary theory of thermal explosion, the calculation formula of estimating the critical temperature of thermal explosion under non-isothermal DSC conditions, and the determination method for the critical temperature of thermal explosion of small-scale solid explosives and its data treatment method [594, 595]. The results of the four methods were in general agreement with each other and the differences were within 5%. The results indicated that the heat-resistance of NTO and that of the common explosives (HMX, RDX, PETN, and tetryl) decreased in the order  $\text{HMX} > \text{NTO} > \text{RDX} > \text{PETN} > \text{tetryl}$ .

Traditionally, the critical temperature  $T_b$  of thermal explosion for energetic materials was estimated using Semenov's thermal explosion theory and the non-isothermal kinetic equation based on Berthelot's expression using reasonable hypotheses. A simpler method can obtain the critical temperature from the onset temperature in non-isothermal DSC curves and rate constants [624]. The results obtained with this method coincided completely with the value of  $T_b$  obtained by Zhang's method [595].

### 8.14.8 Toxicity of NTO

NTO, which is 99.6% pure, was tested for mutagenic potentials with four different *S. typhimurium* strains and one *E. coli* strain by plate incorporation method according to Organisation for Economic Co-operation and Development (OECD) TG 471 at concentrations of 5, 10, 50, 100, and 250  $\mu\text{g}/\text{plate}$  for *Salmonella* strains and 100, 250, 500, 750, and 1000  $\mu\text{g}/\text{plate}$  for *E. coli* without activation [625]. The dose levels were 100, 500, 1000, 2500, and 5000  $\mu\text{g}/\text{plate}$  for both *Salmonella* and *E. coli* with activation. The results showed that NTO was not mutagenic in *S. typhimurium* and *E. coli*, both with and without activation. The negative result was also verified by a confirmatory mutation assay, again both with and without activation.

Testing NTO in a freshwater organism with seven-day survival and reproduction assay concluded that NTO was ranked as practically non-toxic when viewing these results in line with the Chemical Scoring System for Hazard and Exposure Identification [626].

The teratogenicity of NTO in rats was determined by teratogenesis tests. The results showed that the body weight gain in pregnant rats exposed to 2500  $\text{mg}/\text{kg}$  NTO decreased significantly. Corpus luteum formation and embryo implantation numbers also decreased significantly in rats exposed to 156–2500  $\text{mg}/\text{kg}$  NTO compared with the controls [627]. Deformities of fetal development were observed in rats exposed to 2500  $\text{mg}/\text{kg}$  NTO, while bone and viscera deformities were observed in rats exposed to 156–2500  $\text{mg}/\text{kg}$  NTO. It was concluded that NTO showed some teratogenicity in rats in the dose range of 156–2500  $\text{mg}/\text{kg}$ .

The genotoxicity of NTO was investigated using a battery of genotoxicity tests, which included the Ames test, CHO cell chromosome aberration test, mouse lymphoma mutagenesis test, and the rat micro-nucleus test [628]. NTO was not mutagenic in the Ames test or in *E. coli*. NTO did not induce chromosomal aberrations in CHO cells, with or without metabolic activation. In the mouse lymphoma mutagenesis test, all of the NTO-treated cultures had mutant frequencies that were similar to the average frequencies of solvent control-treated cultures, indicating a negative result. The potential *in vivo* clastogenicity and aneugenicity of NTO was evaluated using the rat peripheral blood micro-nucleus test. NTO was administered by oral gavage to male and female Sprague-Dawley rats for 14 d at doses up to  $2 \text{ g kg}^{-1} \text{ d}^{-1}$ . Flow cytometric analysis of peripheral blood demonstrated no significant induction of micro-nucleated reticulocytes relative to the vehicle control (polyethylene glycol, PEG-200). These studies showed that NTO was not genotoxic in either *in vitro* or *in vivo* tests and suggested a low risk of genetic hazards associated with NTO exposure.

The 4-h inhalation median lethal concentration (LC50) of NTO in male and female rats with nose-only exposure to the highest-achievable aerosol atmosphere concentration of NTO (0.18 mg/L) did not induce any compound-related mortality, adverse toxic signs, body weight changes, or gross necropsy findings [629]. A secondary objective was to determine the effect that two different routes of administration (inhalation and oral) had on the absorption of NTO into the bloodstream. Blood samples were collected and analyzed from exposed rats at seven different time points for those exposed via inhalation and six different time points for those given a calculated equivalent oral dose. The results of the blood absorption study indicated that, under these conditions, acute exposure to NTO via inhalation appears to induce higher whole blood NTO concentrations in laboratory rats compared to those exposed via oral gavage.

NTO was administered to male (0, 250, and  $500 \text{ mg kg}^{-1} \text{ d}^{-1}$ ) and female (0, 500, and  $1000 \text{ mg kg}^{-1} \text{ d}^{-1}$ ) Sprague-Dawley rats (15/sex/group) via oral gavage from weaning through puberty to study the effects on pubertal development [630]. Animals were examined daily for the onset of puberty. There were no differences in hormone levels or thyroid follicle and colloid scores between the NTO treatment groups and the control groups. These findings suggested that NTO is not acting as an estrogen or thyroid active compound but may affect steroidogenesis and cause direct testicular toxicity.

Gross external examinations of the offspring of parent rats that had been fed 0, 31, 125, and  $500 \text{ mg NTO kg}^{-1} \text{ d}^{-1}$  via oral gavage for four weeks did not indicate that NTO presents a developmental hazard [631].

## 8.14.9 Applications of NTO

### 8.14.9.1 NTO Applications as an Explosive

NTO is envisioned mostly as an explosive for castable formulations in low-vulnerability warheads [440, 441, 632, 633] and as an ingredient for PBX with proper binders and plasticizers. In Europe, the goal was to obtain a special “CF”

grade (which stands for “Coulé Fondu” in French, which means “Cast Melted ” in English) to be used in melt-cast formulations, where casting viscosity of the molten explosive can induce difficulties to control the filling process and with ensuring the casting of defect-free explosive grains [634]. This special grade can be obtained from a controlled crystallization process whose parameters have been tuned at lab scale and validated at pilot scale. NTO CF is now produced in Europe at an industrial scale, with a highly reproducible bulk density. Other NTO grades are also produced to be used in cast PBX or standard NTO/TNT formulations. Additional information on the applications of NTO as explosives and energetic materials will be included in future solid propellant volumes of the *Encyclopedia of Rocket Propellants*. An insensitive munition explosive formulation (IMX-101) consisted of 3-nitro-1,2,4-triazol-5-one (NTO), 2,4-dinitroanisole (DNAN), and nitroguanidine (NQ). Certain NTO salts are stab-sensitive and may serve as replacements for lead azide or mercury styphnate in percussion caps [635].

#### 8.14.9.2 NTO Derivative Applications as Ballistic Modifiers

The combustion of AP/HTPB composite solid propellants has been studied using the transition metal (Mn, Fe, Co, Ni, Cu, and Zn) salts of NTO as energetic burning rate modifiers [636–638]. The steady burning rate ( $r_b$ ) was considerably enhanced with  $\text{Cu}(\text{NTO})_2$  and  $\text{Fe}(\text{NTO})_2$  but was only moderately enhanced with  $\text{Zn}(\text{NTO})_2$  and  $\text{Co}(\text{NTO})_2$  at low concentration (2mass-%). The activity of these salts has been observed during the isothermal decomposition of AP at 533 K (260 °C). The values of ignition delay, ignition temperature, and the activation energy for ignition of AP were lowered when these salts were added to AP at 2mass-% concentration. The  $r_b$  of the propellants (both highly aluminized and less aluminized), with  $\text{Cu}(\text{NTO})_2$  as an additive at various concentrations, has been determined at high pressures and its activity during combustion was confirmed. The condensed phase activity of  $\text{Cu}(\text{NTO})_2$  during propellant decomposition has also been studied using TGA-DTG techniques.

#### 8.14.9.3 NTO as a Gas Generant

There are many patent applications including NTO as a gas generant, but only one is listed here as an example. Automotive airbag gas generant formulations with NTO provide an alternative to commercially used formulations containing sodium azide. One proposed composition contained 25–75 mass-% NTO [639]. The other principal ingredient of the composition would be 25–75 mass-% of an anhydrous oxidizing salt having a cation selected from metals of Group I-A of the Periodic Table (except sodium), calcium, strontium, or barium, and an anion like nitrate which is essentially free of carbon, hydrogen or halogens.

### 8.15 4-Amino-1,2,4-triazol-5-one

Another triazolone derivative of interest as an energetic material is 4-amino-1,2,4-triazol-5-one (ATO). It can be prepared by reacting phosgene with an acylhydrazide and then reacting the oxadiazolinone with hydrazine hydrate [640]. 4-amino-1,2,4-triazol-5-one can also be prepared by heating carbohydrazide and ethyl orthoformate on a water bath. The slow thermal decomposition of amino 1,2,4 triazol-5-one was measured by DSC and the flash pyrolysis of ATO was investigated by T-jump/FTIR spectroscopy [641].

The molecular structure of 4-amino-1,2,4-triazol-5-one was investigated and a density-functional theoretical computational investigation of its dimers and crystal band structure was done after single crystals suitable for XRD measurement had been obtained by recrystallization from distilled water at room temperature [642, 643]. The H-bond connections make the molecules of ATO form a three-dimensional structure from the solution. The hydrogen bond interactions in the gaseous dimers of ATO were studied by using a DFT computational method. The electron density in the N—NH<sub>2</sub> bond is less than those of other bonds, indicating that it is the weakest one.

The thermal stability of 4-amino-1,2,4-triazol-5-one (ATO) was studied under non-isothermal conditions by DSC in a sealed stainless-steel cell [644]. The melting enthalpy and melting entropy of ATO were  $21.34 \pm 0.49$  kJ/mol and  $46.54 \pm 0.30$  J mol<sup>-1</sup> K<sup>-1</sup>, respectively. The kinetic parameters were obtained from the analysis of DSC curves using several methods. The main exothermic decomposition reaction mechanism of ATO was classified as nucleation and growth, and the kinetic parameters of the reaction were  $E_a = 119.50$  kJ/mol and  $A = 10^{9.03}$  s<sup>-1</sup>. The HOF for ATO was computed by G3 theory. The detonation velocity and detonation pressure were estimated by using the K-J equation, based on the theoretical HOF and the determined crystal density.

The ammonium salt monohydrate of 4,4'-azo-1*H*-1,2,4-triazol-5-one, 4-[(5-oxo-1*H*-1,2,4-triazol-4-yl)azo]-1*H*-1,2,4-triazol-5-one, C<sub>4</sub>H<sub>4</sub>N<sub>8</sub>O<sub>2</sub> (AZTO•H<sub>2</sub>O) was synthesized via potassium permanganate oxidation using 4-amino-1,2,4-triazol-5-one (ATO) as the starting material [645].

4,4'-Azo-1*H*-1,2,4-triazol-5-one ammonium salt

The thermal stability of AZTO•H<sub>2</sub>O was studied by DSC and the kinetic parameters of the non-isothermal exothermic decomposition reaction were calculated by the

Kissinger and Ozawa methods. The results showed that the heat of decomposition, apparent activation energy, and pre-exponential factor of  $\text{AZTO} \cdot \text{H}_2\text{O}$  were 247, 178 kJ/mol, and  $10^{15.74} \text{ s}^{-1}$ , respectively. The critical temperature of thermal explosion and molar heat capacity at 298.15 K for  $\text{AZTO} \cdot \text{H}_2\text{O}$  was 506 K (233 °C) and  $271 \text{ J mol}^{-1} \text{ K}^{-1}$ , respectively. The kinetic rate equation describing the exothermic decomposition reaction of  $\text{AZTO} \cdot \text{H}_2\text{O}$  was

$$\frac{da}{dt} = 10^{15.74} / \beta \times 4(1-a)[- \ln(1-a)]^{\left(\frac{3}{4}\right)} \exp(-1.774 \times 10^5 / RT).$$

### 8.16 Azoxytriazolone

Azoxytriazolone (AZTO) and azotriazolone (azoTO) have been synthesized and characterized by a range of techniques and compared to existing IHE [646]. AZTO is unique in that it does not contain nitro groups like so many other energetic materials. AZTO can be made via electrolysis of aqueous NTO solutions. AZTO showed similar sensitivity to NTO in most tests but had better thermal stability. AzoTO displayed higher thermal and impact stability than AZTO but was more sensitive to ESD.

Azotriazolone

Azoxytriazolone

Attaching two nitro groups, one to each ring, to AZTO gives *N,N'*-dinitro-4,4'-azo-bis-(1,2,4-triazolone) (DNZTO), which is an even more energetic compound, similar to NTO. TGA-DTA and ARC measurements were performed to determine the thermal characteristics and kinetics of the DNZTO decomposition [647]. A single sharp and narrow exothermic decomposition occurred at 416, 423, 429, 430, 433, and 433.4 K (143, 150, 156, 157, 160, and 160.3 °C) at different heating rates (0.5, 1, 2, 3, 4, and 5 °C/min.). This suggests that the DNZTO composition was vulnerable to thermal runaway hazards. The FTIR-TGA-MS results showed that the decomposition products were  $\text{H}_2\text{O}$ ,  $\text{NO}_2$ , NO,  $\text{CO}_2$ , CO, HCN, and  $\text{N}_2\text{O}$ . ARC detected a very low onset temperature at 389.7 K (116.6 °C) and a sharp rise in exothermic reaction at 401 K (128 °C), which was accompanied by a steep adiabatic pressure rise.

## 9 Furazan and Furazan Derivatives

Furazan, also known as 1,2,5-oxadiazole, 2-oxa-1,5-diazole,  $C_2H_2N_2O$ , CAS RN [288-37-9] is a liquid at room temperature that boils at 371 K (98 °C = 208 °F).

In addition to five-membered rings that carry only nitrogen as the heteroatom, there is the family of furazans which carry nitrogen and oxygen atoms in the ring and also form energetic compounds when one or more of the hydrogens are replaced by energetic groups like  $-NO_2$ ,  $-NF_2$ ,  $-N_3$ , or  $-NHNO_2$ . The most readily accessible furazan is 3,4-dimethylfurazan, 3,4-dimethyl-1,2,5-oxadiazole,  $C_4H_6N_2O$ , CAS RN [4975-21-7], which can be prepared by dehydrating dimethylglyoxime. It is a liquid that boils at 427–432 K (154–159 °C).

The main methods for constructing furazan rings are by dioxime dehydration and furoxan reduction. Once the furazan ring is formed, there are reactions of amino-substituted furazan derivatives, nitro-substituted furazan derivatives, and cyano-substituted furazan derivatives (all candidate energetic materials). An overview of the synthesis methods and performance of several typical furazan-based energetic compounds such as dinitro furazan (DNF), diaminoazofurazan (DAAF), 3,4-bis(4'-nitrofurazano-3'-yl)furoxan (DNTF), furazan ethers, and fused-ring furazan energetic compounds (MNOTO, 4,5,9,10-tetranitro-1,4,5,8-tetrazanaphthano (2,3-, 6,7)bisfurazan) provides a good introduction into this field of heterocyclic compound chemistry [648].

### 9.1 3,4-Diaminofurazan

3,4-Diaminofurazan, also known as 3,4-diamino-1,2,5-oxadiazole, 3,4-diamino-1-oxa-2,5-diazole, 1,2,5-oxadiazole-3,4-diamine, DAF,  $C_2H_4N_4O_1$ , CAS RN [17220-38-1],  $M = 100.08$  g/mol, is a precursor used most often for the synthesis of energetic furazan derivatives.

3,4-Diaminofurazan

3,4-Diaminofurazan (DAF) can be prepared by heating diaminoglyoxime (DAG) with potassium hydroxide followed by cooling to give white crystals. DAG as the precursor for diaminofurazan was prepared by adding glyoxal and hydroxylamine hydrochloride into a cooled solution of sodium hydroxide in water. A single crystal of DAG was then cultured by dehydration at high pressure for XRD [649]. The crystals were characterized by XRD, elemental analysis, and FTIR. The crystal habit is monoclinic, space group  $P2_1$  with unit cell parameters of  $a = 0.6763(8)$  nm,  $b = 0.3578(4)$  nm,  $c = 0.9658(12)$  nm,  $\beta = 90.78(2)^\circ$ ,  $V = 0.2338(5)$  nm<sup>3</sup>,  $Z = 2$ , and  $\rho_c = 1.678$  g/cm<sup>3</sup>. DAG melted at 476.6 K (203.5 °C). It has two steps of intense thermolysis between 482–485 and 485–513 K (209–212 and 212–240 °C) and decomposes completely at up to 513 K (240 °C). It is the decomposition of DAG that limits the yield of DAF. Normally DAF is produced by heating DAG and aqueous potassium hydroxide in a pressure bomb at 448 K (175 °C) for 2 h at 2.8 MPa pressure. The conversion of glyoxime into 3,4-diaminofurazan can also be achieved in a one-pot synthesis sequence in good overall yield using microwave irradiation [650].

3,4-Diaminofurazan is an important precursor for the synthesis of furazan-based energetic materials. 3,4-Diaminofurazan was prepared from glyoxal under atmospheric pressure in a yield of 56.4% with a purity of 98.4% [651]. Three convenient methods for the preparation of DAF were compared [652]. The results indicated that DAF can be obtained not only at atmospheric pressure but also at high pressure from the DAG, starting with the amination of glyoxal by a one- or two-step process. The yield (43%) of DAF prepared from glyoxal with other raw materials by only one step is larger than those (11 and 39%) of the other two methods. However, the reaction conditions must be controlled exactly and the reaction time is slightly longer. The process can be scaled up to a 500-g batch size [653].

DAF may be synthesized by the condensation of hydroxylamine with a variety of reagents, including dithiooxamide, cyanogen, glyoxal, or glyoxime to yield DAG. This is followed by cyclization to DAF by treatment with an aqueous base at 453 K (180 °C) in a pressure vessel [654, 655].

DSC and DTA showed that DAF undergoes a two-stage decomposition. The kinetics of the initial stage of thermal decomposition of DAF evaluated from TGA data gave an activation energy of 67 kJ/mol [656].

The thermal stability of DAF was determined by DSC and TGA-DTA [657]. The thermal degradation of DAF occurred in the temperature range of 503–548 K (230–275 °C). The TGA-DTA analysis of DAF indicated that DAF melted at about 455 K (182 °C) before

it decomposed. The influence of the heating rate (5, 10, 15, and 20 °C/min) on the DSC behavior showed that, as the heating rate was increased, decomposition temperatures of the compound also increased.

The hydrogen bonds in 3,4-diaminofurazan connect the molecules into a 3-D network, while hydrogen bonds in 3-amino-4-nitrofurazan connect the molecules into dimer chains [658].

Diaminofurazan contains three nitrogen atoms. With increasing acid strength, not only do the two amino groups that dangle from the ring become protonized, but one of the nitrogens in the ring can become protonized also [659].

Diaminofurazan was evaluated as an additive to nitramine propellants that would desirably reduce the pressure exponent. DSC and DTA revealed that DAF decomposed in two stages. The kinetics of the initial stage of thermal decomposition of DAF evaluated from TG data gave an activation energy ( $E_a$ ) of 67 kJ/mol [656]. The gases that evolved during decomposition contained  $-\text{CN}$ ,  $-\text{NH}$ ,  $-\text{OH}$ , and oxides of nitrogen. The mechanism of pressure coefficient reduction in nitramine propellants by DAG and DAF may involve the intermediate formation of a layer of thermally resistant melon-type multi-ringed polymers in the burning surface of propellants. Such thermally stable products of decomposition are thought to retard heat transfer from the gas phase to the condensed phase.

Two energetic *N*-trinitroethyl-substituted aminofurazans, as well as a nitramine (the *N*-nitration product of one of the amines), were synthesized and characterized by NMR, IR, elemental analysis, XRD, DSC, and TGA [660]. The densities were 1.82–1.87 g/cm<sup>3</sup>. They exhibited good thermal stability ( $T_{\text{dec}} = 432\text{--}503\text{ K} = 159\text{--}230\text{ °C}$ ), acceptable oxygen balance (–15.3%) and high positive HOFs (268–1259.5 kJ/mol). Predicted detonation pressures and velocities for the furazan derivatives were in the range of 35.4–40.8 GPa and 8900–9486 m/s, respectively. The oxidation of DAF by peroxide reagents leads to 3,4-dinitrofurazan [661].

## 9.2 Nitrofurazan and 3,4-Dinitrofurazan

First, 3,4-diaminofurazan (DAF) was prepared from glyoxal under atmospheric pressure in a yield of 56.4% with purity of 98.4% [651]. Next, 3,4-dinitrofurazan (DNF) in a yield of 62.5% with purity of 99.8% was synthesized from DAF by a one-step oxidation process using 50%  $\text{H}_2\text{O}_2$  as an oxidant in the presence of  $\text{H}_2\text{SO}_4$  with an initial concentration of 56.9% at 308 K (35 °C) for 3.5 h. The structure of DNF obtained by this method was then characterized by <sup>13</sup>C NMR, IR, MS, and elemental analysis.

3,4-Dinitrofurazan was synthesized from DAF in concentrated  $\text{H}_2\text{SO}_4$  with 50%  $\text{H}_2\text{O}_2$  as the oxidant in the presence of a tungsten oxide catalyst [662]. At a temperature of 308 K (35 °C), this process significantly increased the DNF yield from 39 to 58%. When compared to the yield with the conventional  $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$  catalyst under the same conditions, this was a significant improvement.

1,2,4-Oxadiazole is an isomer of furazan with a different arrangement of the heteroatoms in a five-membered ring, where only one nitrogen is adjacent to the oxygen atom and the two nitrogens are still separated by a  $-\text{CH}=\text{N}-$  link. 3-Nitro-5-guanidino-1,2,4-oxadiazole (NOG) was synthesized from diaminoglycoluril with *in-situ* generated dimethyldioxirane (DMDO) [663]. The impact sensitivity of NOG was more than 40 J; this coupled with the decomposition temperature of 563 K (290 °C) makes it a truly insensitive explosive. The density of NOG was  $1.766 \text{ g/cm}^3$ , and the enthalpy of formation was  $235.1 \text{ kJ/mol}$ .

The impact sensitivity of polynitrofurazans and similar nitroheterocyclic compounds can be predicted by interpolating between known data and applying structural adjustment factors [148, 149].

The HOFs in the gas phase and detonation properties (including heats of detonation, relative specific impulses, detonation velocities, and crystal densities) of nitrofurazans and nitrofuroxans have been calculated by quantum chemistry, molecular mechanics, and Monte Carlo methods [664]. The crystal densities, detonation properties, and sensitivities of most nitrofurazans and furoxans are high. Therefore, smaller molecules are recommended. The types, orders, and quantities of the linking groups in poly-furazans and poly-furoxans can affect the detonation properties.

### 9.3 3-Amino-4-nitrofurazan

3-Amino-4-nitrofurazan is an oxidation product of 3,4-diaminofurazan. 3-Amino-4-nitrofurazan, also known as  $\text{C}_2\text{H}_2\text{N}_4\text{O}_3$ ; 1,2,5-oxadiazol-3-amine, 4-nitro-; furazanamine, 4-nitro-; ANF, CAS RN [66328-69-6],  $M = 130.06 \text{ g/mol}$ , melts at  $397\text{--}398 \text{ K}$  ( $124\text{--}125 \text{ }^\circ\text{C}$ ).

3-Amino-4-nitrofurazan (ANF) was synthesized from 3,4-diamino-furazan (DAF) by an improved method using oxalic acid with sodium tungstate as a co-catalyst (instead of sulfuric acid) and 30%  $\text{H}_2\text{O}_2$  was used as oxidant (instead of 50%  $\text{H}_2\text{O}_2$ ) [665]. The effects of the reaction temperature, reaction duration, and quantity of the catalyst on the conversion of DAF to ANF were optimized by orthogonal design. The optimal reaction conditions were obtained as follows: the reaction temperature was  $333 \text{ K}$  ( $30 \text{ }^\circ\text{C}$ ), the reaction time was 6 h, and the mol ratio of the co-catalyst to DAF was 1:1. The conversion of DAF was about 33.7% under the optimized reaction conditions.

3-Amino-4-nitrofurazan, 3-amino-3'-nitro-4,4'-azoxyfurazan (ANAF), and 3-amino-3'-nitro-4,4'-azofurazan (ANAzF) can be prepared by oxidizing 3,4-diaminofurazan (DAF), 3,3'-diamino-4,4'-azoxyfurazan (DAAF), and 3,3'-diamino-4,4'-azofurazan (DAAzF), respectively, with an oxidizing mixture of hydrogen peroxide, sodium tungstate or ammonium persulfate, and methanesulfonic acid [ $\text{H}_2\text{O}_2/\text{CH}_3\text{SO}_3\text{H}/\text{Na}_2\text{WO}_4$  or  $(\text{NH}_4)_2\text{S}_2\text{O}_8$ ] to produce above 65% yield of ANF and ANAF and 15% yield of ANAzF [666–668]. The experiments showed that the mixture of  $\text{H}_2\text{O}_2$  and  $\text{Na}_2\text{WO}_4$  or  $(\text{NH}_4)_2\text{S}_2\text{O}_8$  in  $\text{CH}_3\text{SO}_3\text{H}$  media is a new type of efficient

oxidant for the synthesis of compounds with one or more furazan rings with amino and nitro groups as substituents.

3,4-Dinitraminofurazan can be obtained by the nitration of DAF with 100%  $\text{HNO}_3$  [669]. 3-Amino-4-azidofurazan can be prepared by diazotization and substitution of DAF with  $\text{NaNO}_2$ ,  $\text{H}_2\text{SO}_4$ , and  $\text{NaN}_3$ . 3-Azido-4-nitrofurazan and 3,3'-diazido-4,4'-azoxyfurazan can be obtained by the oxidation of 3-amino-4-azidofurazan with 30%  $\text{H}_2\text{O}_2$  and  $\text{Na}_2\text{WO}_4$  in  $\text{CH}_3\text{SO}_3\text{H}$ . The thermal stability of these compounds was studied by TGA-DSC, and their theoretical density, standard enthalpy of formation, detonation velocity, and detonation pressure were predicted by a quantum mechanical computational method. The results showed that the introduction of the  $-\text{N}=\text{N}(\text{O})-$  group enhances the thermal stability of furazan compounds. The introduction of the  $-\text{N}_3$  group improved the standard enthalpy of formation of these compounds. The enthalpy of formation of 3-amino-4-nitro furazan increased from 183.26 to 571.40 kJ/mol after the amino group was transformed to an azido group. The introduction of the nitramino group  $-\text{NHNO}_2$  significantly increased the density, detonation velocity, and detonation pressure of these energetic materials.

DFT and MP2 calculations were made to examine proton transfer in 3-amino-4-nitrofurazan [670]. The results suggested that the A form is the most stable form of 3-amino-4-nitrofurazan in the gas phase and it is the predominant tautomer in solution. In addition, the variation of dipole moments in the gas phase, the specific solvent effects with the addition of one mol of water near the electrophilic centers of tautomers, the transition state of proton transfer assisted by a water molecule, and the potential energy surface were investigated.

#### 9.4 3,3'-Diaminoazofurazan and 3,3'-Diaminoazoxyfurazan

3,3'-Diamino-4,4'-azoxyfurazan, also known as DAAF, DAAOF,  $\text{C}_4\text{H}_4\text{N}_8\text{O}_3$ , CAS RN [78644-89-0],  $M = 212.13$  g/mol, has a density of  $1.747$  g/cm<sup>3</sup> and melts at 522 K (249 °C), which is an unusually high melting point for an energetic material.

3,3'-Diamino-4,4'-azoxyfurazan (DAAF)

DAAF is an energetic compound that has received a lot of attention both as an explosive and as a propellant ingredient also. A series of furazan-based energetic materials derived from 3,4-diaminofurazan (DAF) were synthesized and characterized. These

compounds included diaminoazoxyfurazan (DAAF), diaminoazofurazan (DAAzF), dinitroazoxyfurazan (DNAF), aminonitrofurazan (ANF), dinitrobisfurazanopyrazine (PIPER), and tetrazoxytetrafurazan (TATFO) [671]. Characterization testing included small-scale safety testing (impact, friction, ESD, thermal stability), DSC analysis, VTS, and ingredient compatibility (by DSC). Results from these tests indicated that most of the materials have excellent thermal stability, as determined by DSC analysis. However, the small-scale safety properties and ingredient compatibilities of most of these materials with standard propellant ingredients were found to be unsuitable for an acceptable propellant ingredient. The most promising furazan-based material investigated was DAAF, which was assessed based upon this criteria. The enthalpy of formation of DAAF was +422 kJ/mol (+100.8 kcal/mol) and the density was 1.7426 g/cm<sup>3</sup>. The enthalpy of formation of DAAzF was +500 kJ/mol (+119.4 kcal/mol) and the density was 1.728 g/cm<sup>3</sup>. The enthalpy of formation of DNAF was +775 kJ/mol (+185.3 kcal/mol).

The oxidation of 3,4-diaminofurazan with a variety of peroxide oxidation reagents leads to mixtures of 3,3'-diamino-4,4'-azoxyfurazan (DAAF), 3,3'-diamino-4,4'-azofurazan (DAAzF), and 3-amino-4-nitrofurazan, which can be separated by differing solubilities [672, 673].

Pure DAAF is an orange-yellow crystalline powder with a DSC onset of exotherm at 521 K (248 °C) and an XRD crystal density of 1.747 g/cm<sup>3</sup>. In the drop weight impact sensitivity tester, DAAF was found to have a drop height of greater than 320 cm (2.5 kg, Type 12 tool) and elicited no response to spark (>0.36 J) or friction (>36 kg<sub>f</sub>, BAM). DAAF had a measured  $\Delta H_f = +443$  kJ/mol = +106 kcal/mol. In the Henkin test, the critical temperature was determined to be 514 K (241 °C). The measured detonation velocity was 8.020 mm/ $\mu$ s.

3,3'-Diamino-4,4'-azofurazan, also known as 4-[(Z)-(4-amino-1,2,5-oxadiazol-3-yl)azo]-1,2,5-oxadiazol-3-amine, DAAzF, C<sub>4</sub>H<sub>4</sub>N<sub>8</sub>O<sub>2</sub>, CAS RN [78644-90-3], *M* = 196.13 g/mol, has a density of 1.736 g/cm<sup>3</sup> and melts at 598 K (325 °C) with decomposition, which is an unusually high melting point for an energetic material.

3,3'-Diamino-4,4'-azofurazan (DAAzF)

Although the azo-compound, 3,3'-diamino-4,4'-azofurazan (DAAzF), has less available oxygen than the azoxy compound DAAF, it has a higher measured enthalpy of formation,  $\Delta H_f$  (+535 kJ/mol = +128 kcal/mol). Other sources give the enthalpy of formation as +522 kJ/mol (+124.9 kcal/mol = +637 cal/g).

The detonation velocity of DAAzF was determined to be 7.6 km/s at a packing density of 1.65 g/cm<sup>3</sup>. The thermal stability of DAAzF was also attractive, with it having a DSC onset of 588 K (315 °C), which is much higher than that of DAAF. The DAAzF, a dark-orange crystalline solid, was found to be insensitive to impact (H50 >320 cm, Type 12 tool), spark (>0.36 J), and friction (>36 kg<sub>f</sub>, BAM). DAAzF cannot be initiated by laboratory impact drop tests. However, it has, in some aspects, better explosive performances than 1,3,5-triamino-2,4,6-trinitrobenzene (TATB), which is generally considered to be the standard of IHE. The explosive performance of DAAzF was lower in both velocity and pressure as the increase in HOF was not sufficient to offset the drop in oxygen balance compared to DAAF [674, 675].

The decomposition mechanism of DAAzF was examined by DSC with different heating rates (see also [676]). It was found that the values of the activation energy  $E_a$  for DAAzF decomposition were 336.8 and 329.7 kJ/mol, as calculated by Kissenger's method and Ozawa's method, respectively, and the value of  $\ln A$  was 67.535 [677].

3,3'-Diamino-4,4'-azoxyfurazan process optimization studies were performed to improve the original synthesis method and to address issues with purity and manufacturability. Previously, only recrystallization would result in the desired particle size. Ultimately, a complete solution to all observed issues was found with a new synthesis process. This allowed DAAF to be prepared without any impurities, with good particle size distribution, and without the need for recrystallization. All that was made possible along with the production of a minimum of hazardous waste [678–680].

The compatibility of DAAzF with other energetic materials was studied by using a pressure DSC method [681]. The energetic materials included HMX, RDX, NC, NG, DINA, aluminum powder, and 3,4-dinitrofurazanfuroxan (DNTF). The results showed that there were deleterious interactions between DAAzF and DNTF, DINA, HMX, or RDX, while only weak interactions between DAAzF and NC, NG, NC+NG, or Al were seen. According to the evaluated standard of compatibility, the binary systems of DAAzF with NC, NG, NC+NG, and Al are compatible, but the binary system of DAAzF with DNTF is outright hazardous.

3,3'-Diamino-4,4'-azoxyfurazan (DAAF) along with 1,4-dihydrazino tetrazine (DHTz) and 3,3'-azobis(6-amino-1,2,4,5-tetrazine) (DAAT) were synthesized and characterized by IR, NMR, MS, TGA-DTA, DSC, TGA-FTIR, and impact and friction sensitivity tests [682]. DAAF is insensitive to mechanical stimuli whereas DAAT and DHTz are vulnerable to impact stimuli. The theoretical explosive power of DAAF, DAAT, and DHTz alone and their combinations with well-known IHE as well as that of propellants based on them were calculated.

The thermal decomposition of DAAzF has been investigated under isothermal conditions at 473–593 K (200–320 °C) using thin-walled glass manometers of the compensation type (spoon gauge, Bourdon gauge) [683]. The kinetic equation of DAAzF decomposition in the solid state was

$$k = 5.0 \times 10^{11} \exp(-21320/T) \text{ s}^{-1}$$

and in the gas phase it was

$$k = 3.3 \times 10^{12} \exp(-21020/T) \text{ s}^{-1}.$$

Based on the burning rate and thermocouple measurement data, rate constants of DAAzF decomposition in the molten layer at 873–1073 K (600–800 °C) have been derived from a condensed-phase combustion model

$$k = 4.6 \times 10^8 \exp(-16680/T) \text{ s}^{-1}$$

which was in good agreement with kinetic data obtained in solution at 235–260 °C. The mechanism of DAAzF thermolysis and combustion includes initial rupture of the C–N bond between the azo-group and furazan ring, with subsequent nitrogen evolution and decomposition of the heterocyclic ring. In the combustion wave, the heat release from the decomposition of the stable furazan ring follows the heat release from the azo-group decomposition, thus resulting in a distinct two-stage flame structure. Previously, the only kinetic data of DAAzF thermal decomposition ( $E = 336.8 \text{ kJ/mol}$ ,  $A = 10^{26.4} \text{ s}^{-1}$ ) had been obtained in non-isothermal conditions using DSC. Based on all indications, these were characteristic of a total process of DAAzF decomposition in both solid and gas phases accompanied by evaporation, rather than characteristic of the DAAzF breaking bonds strength. The rate constants  $k$  of DAAzF decomposition were calculated as a ratio of the initial gas evolution rate to the final volume of gases. In the  $\ln k$  vs. reciprocal temperature co-ordinates in an Arrhenius-type graph, the experimental points fell on a straight line, as described by the following equation:

$$k = 7.8 \times 10^{20} \exp(-32680/T) \text{ s}^{-1}.$$

Vapor-pressure data of DAAzF derived from thermocouple measurements of burning surfaces are shown in Figure 9 in comparison to those of NTO.

Many more energetic compounds carry aminofurazan building blocks. Some contain three or more furazan rings lined up like pearls on a necklace while others have multiple fused rings like a spider web or caged structures like a diamond [684].

The *trans*- and *cis*-isomers of azofurazan and azoxyfurazan may differ in their thermal stability. One or the other may be the first one to decompose when heated. DFT calculations were performed to understand the thermal *trans-cis* isomerization and initial thermal decomposition of DAAzF, DAAF, 3,3'-dinitro-4,4'-azofurazan (DNAzF), and 3,3'-dinitro-4,4'-azoxyfurazan (DNAF or DNOAF) [685]. The relative energy between the *trans*- and *cis*-isomer was calculated. It was found that a negative correlation existed between the relative energy and the sensitivity for these energetic azofurazan and azoxyfurazan compounds, where the higher relative energy means the lower the sensitivity. It was also found that the oxidation of the azo-group to an azoxy group could cause the decrease in the relative energy between the *trans*- and *cis*-isomer, as well as the alteration of the isomerization mechanism. An inversion mechanism operates for azofurazan compounds (DAAzF and DNAF) while a rotation mechanism works for azoxyfurazan compounds (DAAF and DNOAF). The energy of an external stimu-

lus should firstly trigger the *trans-cis* isomerization, rather than the breakage of C—N bond.

DFT calculations indicated that DAAzF is more stable than DAAF [686]. In addition to this, the oxidation of the azo group has a significant influence on the energy difference between *trans*- and *cis*-isomer of azofurazan. The energy difference between the isomers of DAAF is only about half of that of DAAzF. A self-desensitization effect could be responsible for the low sensitivity of azofurazan. This desensitization mechanism may be useful in the design of other high energetic density materials.

Instead of sulfuric acid/hydrogen peroxide oxidation of aminofurazans to azofurazans, electrochemical anodic oxidation has been shown to be an effective tool for the oxidation of aminofurazans to azofurazans in ca. 1% aqueous alkali solution at room temperature [687]. The electrochemical reaction is simple and convenient, eliminating the use of expensive and toxic organic or inorganic oxidants. The green economic preparation of desired azo compounds is very clean, producing only H<sub>2</sub> as a result of cathodic reduction.

A good survey paper reviewed the synthesis, properties, performance, and safety characteristics of DAAF and 18 formulations based on it [688]. Though DAAF has only a moderate crystal density, it offers a highly positive HOF and, hence, superior performance when compared to TATB. It is friction and impact insensitive but is more sensitive to shock than TATB and has an exceptionally small critical diameter (3 mm). It performs very well at low temperatures unlike other insensitive explosives (see also [689]).

The conversion of DAF to DAAF would best be performed in a solvent in which DAF is very soluble and DAAF is not. The solubilities of DAF and DAAF were investigated by high-pressure liquid chromatography with ultraviolet detection in water, dichloromethane, acetonitrile, ethyl acetate, methanol, and acetone between 293 and 313 K [690]. This helps to select the best solvent for the preparation and recrystallization of DAAF.

The heat capacity of 3,3'-diamino-4,4'-azofurazan (DAAzF) was determined by DSC. In the temperature range of 253–373 K, the heat capacity ( $c_p$ ) versus  $T$  relationship can be fitted into a linear equation, as follows:

$$c_p = 0.0028T + 0.26456$$

where  $c_p$  is the heat capacity in J g<sup>-1</sup> K<sup>-1</sup> and  $T$  is the temperature in kelvin [691]. The standard molar heat capacity is 215.53 J mol<sup>-1</sup> K<sup>-1</sup> at 298.15 K. Thermodynamic functions of DAAF, including enthalpy, entropy, Gibbs free-energy increments, and differential functions [ $H_T - H_{298.15}$ ], [ $S_T - S_{298.15}$ ], and [ $G_T - G_{298.15}$ ] were calculated. The combustion energy of DAAF was measured in an oxygen-bomb calorimeter and was found to be  $\Delta U_c = -(13188.43 \pm 32.77)$  J/g. The standard molar enthalpy of combustion at 298.15 K was determined to be  $\Delta H_c = -(2575.68 \pm 6.42)$  kJ/mol. The standard molar enthalpy of formation was calculated to be  $\Delta H_f = +429.98 \pm 6.44$  kJ/mol. The detona-

tion velocity and detonation pressure were calculated as 7.31 km/s and 23.61 GPa using the Kamlet-Jacobs equations and the experimental enthalpy of formation.

Connecting two furazan rings without an intermediate azo or azoxy bridge gives bifurazan compounds, which have also been tested as propellant ingredients. One intermediate for the synthesis of other bifurazans is 4,4'-diamino-3,3'-bifurazan. This can be made in a one-pot synthesis from 3,4-di(hydroximinomethyl)furoxan and hydroxylamine, with pH increasing over the course of the reaction from 1 to 10 [692]. Oxidation of 4,4'-diamino-3,3'-bifurazan with trifluoroacetic acid/H<sub>2</sub>O<sub>2</sub> gives 4,4'-dinitro-3,3'-bifurazan. This has a density of 1.85 g/cm<sup>3</sup>, melts at 358 K (85 °C), and has a drop weight sensitivity H<sub>50</sub> similar to that of PETN.

### 9.5 Nitroazofurazan and Nitroazoxyfurazan

Nitroazofurazan and nitroazoxyfurazan are of interest as nitrogen-rich compounds without any hydrogen. Their combustion products would not contain any water, which sometimes interferes with the operation of chemical lasers. These compounds would therefore be useful as gas generants for chemical lasers. 3,3'-Azoxybis(4-nitrofurazan), 3,3'-azobis(4-nitrofurazan), and 3,3'-bis(4-nitrofurazan) were patented as propellant ingredients [693]. The synthesis of the dinitrated bifurazans is described in the literature. In the case of 3,3'-azoxybis(4-nitrofurazan), C<sub>4</sub>N<sub>8</sub>O<sub>7</sub>, see [694].

Both diaminofurazan (DAF) and diaminoazofurazan (DAAzF) were converted to dinitroazoxyfurazan, 3,3'-azoxybis(4-nitrofurazan) (DNAF) in oxidations with a mixture of ammonium persulfate and hydrogen peroxide in concentrated sulfuric acid.

3,3'-Azoxybis(4-nitrofurazan)

3,3'-azobis(4-nitrofurazan), (Z)-bis(4-nitro-1,2,5-oxadiazol-3-yl)diazene, C<sub>4</sub>N<sub>8</sub>O<sub>6</sub>, *M* = 256.093 g/mol, can be made by reaction of a dinitrofurazan with a base of acetonitrile [695].

3,3'-Azobis(4-nitrofuran)

3,3'-Bis(4-nitrofuran),  $C_4N_6O_6$ , can be synthesized by oxidation of 4,4'-diamino-3,3'-bifurazan [654]. Diaminofurazan (DAF) generated from glyoxal can be oxidized by a mixture of hydrogen peroxide and concentrated sulfuric acid to produce diamino-azoxyfurazan (DAAF), which was subsequently oxidized to form dinitroazoxyfurazan (DNAF) [696]. The total yield of DNAF was 11%.

The synthesis of 3,3'-diamino-4,4'-azofurazan (DAAzF), 3,3'-diamino-4,4'-azoxyfurazan (DAAF), and 3,3'-dinitro-4,4'-azoxyfurazan (DNAF) was improved. The yield of the prepared DAAzF by using a different oxidant can reach 65.6% [697]. The compounds were characterized by DSC-TG elemental analysis, IR,  $^1H$  NMR, and MS methods. The results showed that the sensitivity of DNAF explosives is high but DAAzF and DAAF explosives have low sensitivity.

MO quantum chemical computations of the molecular structure and thermal decomposition of 3,3'-dinitro-4,4'-azoxyfurazan (DNAF) and a geometry optimization showed that *trans*-DNAF has a twisting configuration due to the substituted  $NO_2$  on the furazan rings and the oxidation of the azo-group [698]. The BDE of the two C—N bonds which connect the furazan rings and azoxy-group were found to be 276 and 385 kJ/mol (65.9 and 92 kcal/mol), respectively. This suggests that the C—N bond on the side of O-atom of the azoxy-group is relatively weak.

Other sources reported that DNAF has a density of 1.91 g/cm<sup>3</sup>, a standard molar enthalpy of formation of 640 kJ/mol, a detonation velocity of 9390 m/s, and a detonation pressure of 40.5 GPa (see also [699]).

## 9.6 Nitroaminofurazans

The structural, electronic, and physicochemical properties of 4,4'-bis(nitramino)-azofurazan with a density of 1.89 g/cm<sup>3</sup> and 4,4'-bis(nitramino)azoxyfurazan with a density of 1.96 g/cm<sup>3</sup> as HEDMs were compared and a new family of nitrogen-rich energetic salts based on these two nitroaminofurazans were synthesized and fully characterized [700]. Based on experimental evidence and theoretical calculations, 4,4'-bis(nitramino)azoxyfurazan and its ionic derivatives were found to exhibit higher detonation velocities and pressures and higher densities than their azofu-

razan analogues. This supports the added value of introducing the *N*-oxide moiety into energetic materials.

4,4-Dinitramino-3,3-azofurazan

4,4-Dinitramino-3,3-azoxyfurazan

3-Nitramino-4-nitrofurazan, *N*-(4-nitro-1,2,5-oxadiazol-3-yl)nitramide, has a density of 1.93 g/cm<sup>3</sup> and forms salts with many bases such as ammonia, hydroxylamine, hydrazine, and TNAZ [701]. 3-Nitramino-4-nitrofurazan melts at 333 K (60 °C) and starts decomposing at 374 K (101 °C). The heat of combustion is 6556 J/g (1567 cal/g), which corresponds to a HOF of +251 kJ/mol (+60 kcal/mol). There is only one hydrogen in the entire molecule and that is the one that makes it an acid that forms salts with many different bases. For instance, the hydroxylammonium salt has a density of 1.875 g/cm<sup>3</sup> and starts decomposing at 436 K (163 °C) [702]. This salt has a heat of combustion of 1648 cal/g, which corresponds to a HOF of +75.3 kJ/mol (+18 kcal/mol). 3-Nitramino-4-nitrofurazan and its salts are suitable as propellant ingredients.

3-Nitramino-4-nitrofurazan

3,3'-Diamino-4,4'-bifurazane, 3,3'-diaminoazo-4,4'-furazane, and 3,3'-diaminoazoxy-4,4'-furazane were nitrated in 100%  $\text{HNO}_3$  to produce the corresponding 3,3'-dinitramino-4,4'-bifurazane, 3,3'-dinitramino-4,4'-azofurazane, and 3,3'-dinitramino-4,4'-azoxyfurazane, respectively [703]. The neutral compounds showed very imposing explosive performance but possess lower thermal stability and higher sensitivity than RDX. More than 40 nitrogen-rich compounds and metal salts derived from these nitramines were prepared and characterized by low-temperature XRD, IR and Raman spectroscopy, multi-nuclear NMR, DSC, and elemental analysis. Calculated energetic performances using the EXPLO5 code, based on calculated HOFs and X-ray densities, showed promising high energetic performances of the nitraminofurazanes as energetic materials. The sensitivities towards impact, friction, and ESD were also tested.

The spontaneous Raman scattering by the products of hydrazinium 3-nitro-4-nitraminofurazanate decomposition on a rapidly heated platinum filament was used to identify intermediate products of the decomposition reaction. This is a new method that is similar to the frequently used T-jump/FTIR method [704].

## 9.7 Multi-Ringed Furazans

Now that single-ringed furazans have enabled the synthesis of a series of energetic compounds, investigations have extended the search to multi-ringed, catenated, or annulated furazan derivatives. Part of that effort was already rewarded in the synthesis of compounds that contain two furazan rings bridged by an azo or azoxy group. Other compounds are linked by C—C or C—N bonds. DFT computational methods were used to study the HOFs, electronic structure, energetic properties, and thermal stability for a series of bridged difurazan derivatives with different linkages and substituent groups [705]. The results showed that the  $-\text{N}_3$  group and azo bridge ( $-\text{N}=\text{N}-$ ) play a very important role in increasing the HOF values of the difurazan derivatives. The calculated energetic properties indicated that the  $-\text{ONO}_2$ ,  $-\text{NO}_2$ ,  $-\text{NF}_2$ ,  $-\text{N}=\text{N}-$ , or  $-\text{N}(\text{O})=\text{N}-$  groups are effective structural units for enhancing the detonation performance for most of the furazan derivatives. An analysis of the BDE for several relatively

weak bonds suggested that the N–O bond in the ring is the weakest bond and that ring cleavage is likely to happen early on in thermal decomposition. Overall, the –NH–NH–, –N=N–, or –N(O)=N– group were confirmed as known effective bridges for enhancing the thermal stability of furazan derivatives.

3,4-Bis(4-nitro-1,2,5-oxadiazol-3-yl)-1,2,5-oxadiazole-*N*-oxide (BNFF) can be prepared from the amine by slow oxidation with hydrogen peroxide.

3,4-Bis(4-nitro-1,2,5-oxadiazol-3-yl)-1,2,5-oxadiazole-*N*-oxide (BNFF)

High-energy materials based on isomeric dinitrobi-1,2,5-oxadiazole structures comprising nitrofurazan and nitrofuroxan sub-units were synthesized [706]. Due to planarity and strong non-covalent interactions, these materials display high-density values, as determined by single-crystal XRD. The thermal, impact, and friction sensitivities of both isomers were similar to that of nitroesters. Their high detonation performance along with high density, high HOF, and good oxygen balance make these compounds promising as explosives and high-energy oxidizers.

DFT computations were made to predict the enthalpies of formation, energetic properties, and thermal stability for a series of furazano[3,4-*b*]pyrazine derivatives with different substituents or nitrogen-containing heterocycles [707]. It was found that –N<sub>3</sub> or nitrogen-containing heterocycles improve the energy content of these derivatives. The calculated detonation velocities and detonation pressures indicated that the insertion of –NO<sub>2</sub>, –NF<sub>2</sub>, or –NO<sub>2</sub>-substituted heterocycles will enhance the detonation performance. An analysis of the BDE for relatively weak bonds suggested that most of the derivatives were expected to have good thermal stability. The N–O bond in the furazano[3,4-*b*]pyrazine ring is the weakest bond. Ring cleavage may happen as the first step in thermal decomposition.

## 10 Oxazole and Oxadiazole Derivatives

### 10.1 Oxazole Derivatives

Oxazoles contain one oxygen atom and one nitrogen atom in a five-membered ring. The heteroatoms are usually in the 1,2-positions. Tetrakisnitroxymethylbiisoxazole, bis-isoxazole tetramethylene tetranitrate, 3,3'-biisoxazole-4,4',5,5'-tetrakis(methyl nitrate),  $C_{10}H_8N_6O_{14}$ , BITN, and bisnitroxymethylbiisoxazole, 3,3-bis-isoxazole-5,5'-bis-methylene dinitrate,  $C_8H_6N_4O_8$ , BIDN, are new energetic materials with promising properties and easy synthesis routes [708–710].

Tetrakisnitroxymethylbiisoxazole

### 10.2 Oxadiazole Derivatives

Quantum chemical calculations for 3,3'-bi-1,2,4-oxadiazole derivatives with difluoronitromethyl, fluorodinitromethyl, and trinitromethyl groups have been carried out and they predict promising energetic performances for both explosive and propulsive applications [711, 712].

(5-Nitroimino-4-hydro-1,3,4-oxadiazol-2-yl)methyl nitrate has a high density of  $1.898 \text{ g/cm}^3$  at 149 K [713]. (5-nitroimino-4-hydro-1,3,4-oxadiazol-2-yl)methyl nitrate and 4-amino-1,2,4-triazolium(5-nitroimino-4-hydro-1,3,4-oxadiazol-2-yl) methyl nitrate have low melting points (359.82 and 358.8 K = 86.67 and 85.65 °C), which make them suitable for use as melt-cast explosives.

## 11 Tetrazoles

### 11.1 Tetrazole

Tetrazole, also known as *1H*-tetrazole, *2H*-tetrazole,  $\text{CH}_2\text{N}_4$ , CAS RN [288-94-8],  $M = 70.053 \text{ g/mol}$ , is the parent molecule of a wide range of high-nitrogen chemicals that are very useful as gas generants and propellant ingredients. Tetrazole itself is not used as such; it is mostly utilized in the form of substituted tetrazoles and their salts. Triazole compounds are often not energetic enough and pentazole remains largely a wishful thought due to its predicted instability. Neither of the two five-membered ring compounds are used in gas generants. Tetrazoles are positioned in the family of five-membered ring heterocyclic amines and they have sufficient energy, high nitrogen content, and are yet stable enough to be handled safely. The most straightforward method for the synthesis of *1H*-tetrazole is the reaction of sodium azide with ammonium chloride and orthoethyl formate in glacial acetic acid.

Tetrazole is the core ring structure for numerous tetrazole derivatives which are valuable as sources of nitrogen in gas generants and as building blocks for HEDMs. The properties of tetrazole compounds have been summarized in several books and review publications, including: [2, 714–718]. The Fedoroff *Encyclopedia of Explosives and Related Items* contains sections on numerous tetrazoles [719]. Open-chained compounds with a composition similar to tetrazole  $(\text{CH}_2)_n\text{N}_4$  were once called “tetrazotic acid,” but this compound is known only in the form of some of its derivatives. These should not be confused with the ring-closed tetrazole derivatives.

#### 11.1.1 Preparation of Tetrazole and Tetrazole Derivatives

A versatile method of preparing 1-alkyl tetrazoles is by reaction of primary amines with ethylorthoformate and sodium azide, resulting in the formation of 1-monosubstituted tetrazoles.

Bifunctional alkylenediamines react easily and involve both amino groups, thus resulting in the formation of the corresponding bistetrazolyl derivatives with an alkylene group in the middle.

Syntheses requiring hydrogen azide as a reactant are dangerous due to the explosive nature of hydrogen azide. Position-5-substituted alkyltetrazoles can be safely prepared in a continuous method in a micro-flow reactor with dwell times of two to three minutes at 533 K (260 °C) [720].

Various tetrazole derivatives can be obtained by reaction of diaminoguanidine with nitrous acid [721, 722].

### 11.1.2 Physical Properties of Tetrazole

1*H*-Tetrazole forms colorless crystals that melt at 430–431 K (157–158 °C), have a density of 1.477 g/cm<sup>3</sup>, and sublime (boil) at 493 ± 23 K (220 ± 23 °C). Other sources listed the melting point as 429.6 K (156.5 °C). The vapor pressure of tetrazole in the range 333–404 K can be expressed by the equation

$$\ln P = 31.215 - 10586/T$$

where *P* is the vapor pressure in Pascal and *T* is the temperature in kelvin.

Tetrazole and substituted tetrazoles are amphoteric (amphiprotic) compounds that can form salts with strong acids as well as strong bases. Tetrazolium and tetrazolate salts will be discussed in a later section. We have to first summarize the physical and chemical properties of the neutral non-ionized compounds; although these are only of academic interest, they are often cited in comparison to the substituted compounds which are of interest as rocket propellants and explosives.

#### 11.1.2.1 Molecular Structure of Tetrazole

The tetrazole ring structure is stabilized through resonance as a pseudo-aromatic ring. The stability varies with the type of substituents and depends on the loss or addition of protons, forming tetrazolium cations or tetrazolate anions. The numbering of positions in the tetrazole molecule starts at one of the terminal nitrogens and continues in the direction of the adjacent nitrogens, leaving the sole carbon atom in position five.

5*H*-Tetrazole

1*H*-Tetrazole and 2*H*-tetrazole are a tautomeric pair and are aromatic while 5*H*-tetrazole is not. The stability of tetrazole is indicated by the relatively high melting point, 428 K = 155 °C, without decomposition, and the relative stability of the ring compound in chemical reactions involving side groups, e.g., the diazotization of 5-aminotetrazole. The apparent stability of the tetrazole ring indicates that a considerable resonance or stabilizing energy must be present in the system.

The names, formulas, and XRD powder patterns of 29 tetrazole derivatives from known materials were summarized in a publication to identify the crystal structures [723]. A summary of the IR spectra of nitrogen-rich organic compounds contains IR spectra of tetrazole and several tetrazole derivatives [722]. The IR spectrum of tetrazole is shown in Figure 14. The IR spectrum does not contain many characteristic features because the molecule is so symmetrical.

**Figure 14:** Infrared spectrum of tetrazole. (Reproduced and modified from [722], with permission from the Levering Estate.)

XRD analyses and MO calculations of 1*H*-tetrazole were carried out to explain its high stability [724]. Based on XRD results, the five bonds in the ring have been found to have intermediate lengths (between single and double bond lengths). The 1*H*-tetrazole molecule is quite stable because of its aromaticity. The N1—C5 distance of 1.315 Å is significantly shortened compared to the N—C bond in pyrrolidine. The molecular structure, which was calculated by the *ab initio* MO calculation of one 1*H*-tetrazole molecule at MP2/6-31G\* level, showed a good agreement with experimental results except for the abnormally short N1—C5 distance. Calculations of dimers and trimers showed that 1*H*-tetrazole can be stabilized by a strong intermolecular electrostatic interaction between the protons and the delocalized electrons over the ring.

Over the years, the tetrazole moiety has become a strategic group in many industrial applications like gas generants, propellants, and pharmaceuticals. Tetrazoles are

well established as high-nitrogen compounds in gas-generant and propulsion applications.

In addition to forming tetrazolium and tetrazolate salts where protons are exchanged, the neutral tetrazole molecule as a ligand can surround a central metal atom in tetrazolo metal salt complexes. 1*H*-tetrazolo (1HT)-metal complexes were investigated as gas generants for airbag inflators [725]. Thermal stability DSC measurements, sensitivity tests, and deflagration tests were conducted to investigate the influences of the metals on the decomposition characteristics of the complexes. The DSC measurements revealed that the 1HT-metal interaction stabilized the complexes. The deflagration tests indicated that the metals in the substance had a substantial impact on the burning rate.

#### 11.1.2.2 Molecular Structure of Tetrazole Derivatives

DFT computations were performed to study the HOFs, electronic structure, energetic properties, and pyrolysis mechanism of a series of heterocyclic amines, including triazole, tetrazole, furazan, tetrazine, and fused heterocycles [726]. It was found that tetrazole and tetrazine are effective structural units for increasing the  $\Delta H_f^\circ$ 's of the derivatives. Seventy-one compounds had better predicted detonation properties than RDX and 25 compounds had better predicted detonation properties than HMX.

Several observations in the literature indicate that the reactivity of side-chain substituents on tetrazoles (and other azoles as well) depends strikingly on whether the trivalent (pyrrole-type) nitrogen atom is located at the 1- or the 2-position of the tetrazole ring. This dependence has been observed in decarboxylation, hydrogen exchange, diazotization, nucleophilic substitution, and other reactions. Physical measurements have been carried out on several tetrazole derivatives using  $^1\text{H}$ ,  $^{19}\text{F}$ , and  $^{13}\text{C}$  NMR, and dissociation constants were measured on a group of isomeric pairs of tetrazole derivatives [727].

#### 11.1.2.3 Thermodynamic Properties of Tetrazoles

The HOFs and densities of thirteen different tetrazole derivatives were measured and evolved gas volume, adiabatic flame temperature, and predicted product gas composition for burning mixtures with copper(II) oxide were calculated through chemical equilibrium calculations using these values [728]. Closed bomb tests were conducted for each mixture to measure the pressure-time history and the temperature-time history of burning pellets. There was a good correlation between the theoretical amounts of generated gases and the maximum pressure. It was found that the rate of gas release of six of the tetrazole derivatives can be better than that of the currently used 5-aminotetrazole (5-AT). In some instances, HCN,  $\text{NO}_2$ , and  $\text{NH}_3$  were found in the exhaust gas even though these toxins were not predicted theoretically. There are two literature values for the  $\Delta H_f^\circ$  of 1*H*-tetrazole of 334.3 kJ/mol (79.9 kcal/mol) and 320.5 kJ/mol (76.6 kcal/mol). The lower value may be in error due to the existence of tautomers in the gas phase.

**Table 44:** Heats of combustion and enthalpies of formation of tetrazole and tetrazole derivatives.

| Compound name              | Gross formula                                               | Heat of combustion |               | Enthalpy of formation |          |
|----------------------------|-------------------------------------------------------------|--------------------|---------------|-----------------------|----------|

Data Source: [249].

The heats of combustion of a wide range of triazole and tetrazole derivatives were determined in a combustion bomb calorimeter. The enthalpies of formation can be derived from these numbers [249, 250] (Table 44). A continuation of this effort provided data for 36 additional high nitrogen compounds [250].

A computational approach to the prediction of the HOFs of energetic salts from electronic structure and VBT calculations used as its starting point reliable  $\Delta H_f^\circ$  data for energetic precursor molecules [167]. The  $\Delta H_f^\circ$  of more complex energetics species such as substituted imidazole, 1,2,4-triazole, and tetrazole molecules containing methyl substituents were calculated in this way and compared to experimental data (Table 45).

Tetrazole and tetrazole derivatives are the basis of many energetic materials due to their 80% nitrogen content, thermal stability, and high enthalpy of formation. A structure-property relationship study focused on the optimized geometries of tetrazole derivatives obtained from DFT calculations [729, 730]. The HOFs of tetrazole derivatives were calculated by designing appropriate isodesmic reactions. The increase in **nitro groups** on azole rings demonstrated a remarkable increase in the enthalpy of formation. Density can be predicted by using a consistent valence force field (CVFF) method. An increase in the number of nitro groups increased the density. Detonation properties of the designed compounds were evaluated by using the K-J equation based on predicted densities and the enthalpy of formation. Designed tetrazole derivatives showed predicted detonation velocities of over 8 km/s and detonation pressures of about 32 GPa. Thermal stability was evaluated via BDE of the weakest C—NO<sub>2</sub> bond.

**Table 45:** Comparison of calculated and experimental gas-phase enthalpy of formation of some neutral tetrazole derivatives.

| Compound                  | Enthalpy of formation, calculated |          | Enthalpy of formation, measured |             |

### 11.1.3 Chemical Properties of Tetrazole

Tetrazole can be easily deprotonated using common bases such as ammonia, hydrazine, or alkali and alkaline earth metal hydroxides or carbonates forming the corresponding tetrazolate salts of these bases.

In ionic compounds, the tetrazolate ion can often take the place of the azide moiety where it releases a comparable amount of energy upon combustion. However, in covalent bonds in organic compounds, the tetrazole group is more stable and versatile than the azido group. It can also be modified by substitution on the ring to produce a wide range of materials with different  $pK$  values.

Special interest has been devoted to the tetrazolium tetrazolate salts in which one of the tetrazole rings carries a positive charge and the other a negative charge (see also [10]). EILs based on the tetrazolium cation have also been reported (see *Encyclopedia of Liquid Fuels*, chapter “Cyano Compounds and Nitriles”). Although these appear attractive, they can be prepared only via multi-step syntheses. Tetrazoles have been used to develop a wide range of highly energetic ionic liquids. Tetrazole compounds are important energetic materials for applications in gas-generating agents and tetrazole polymers in solid propellants [731].

#### 11.1.3.1 Thermal Stability and Thermal Decomposition of Tetrazole

Tetrazole melts at 429.6 K (156.5°C) and starts decomposing soon thereafter. The kinetic parameters of the thermal decomposition of tetrazole (5,5'-bitetrazole, and 5-alkyl-, and 5-aryl-substituted tetrazoles) in melts of neat substances and nitrobenzene solutions have been determined using a manometric method [732]. The proposed mechanism involves limiting stages of the monomolecular decomposition, which determine the observed rate of nitrogen formation, proceeding to the fast reversible transformation of the 1*H*- and 2*H*-forms and the reversible opening of the

2*H*-form followed by the formation and subsequent cleavage of the corresponding intermediate diazo compound.

The thermal decomposition of 1*H*-tetrazole has been examined at various heating rates and different endpoint temperatures [733]. A pyroprobe was used as a heating device and the gaseous decomposition products were analyzed by FTIR. As a result, two different mechanisms for the thermal decomposition of 1*H*-tetrazole were proposed, which are dependent on the decomposition temperature. At the lower decomposition temperature, the most likely start of 1*H*-tetrazole decomposition is the cleavage of C5—N1 and N3—N4 bonds. This is because HCN and HN<sub>3</sub> will be detected as decomposition products at lower temperatures. At the higher decomposition temperature, various decomposition reactions may occur simultaneously to form such products as HCN, NH<sub>3</sub>, CH<sub>4</sub>, and C<sub>2</sub>H<sub>2</sub>.

A very good summary of the various reaction paths taken by tetrazole and tetrazole derivatives during their thermal decomposition is given in Reference [718]. One of the potential reaction products is the thermally more stable melamine. There are several publications about the decomposition of tetrazole itself [734–736].

The thermal stability, product composition, and decomposition mechanism of some polymeric and low-molecular tetrazoles as well as sigma-complexes [PdCl<sub>2</sub>L<sub>2</sub>] (L = low-molecular or polymeric tetrazole ligand) were investigated by TGA, evolved gas volumetry, MS, IR, and UV spectrometry [737]. The kinetic and activation parameters of the decomposition were determined over a wide temperature range in a vacuum, air, and inert atmosphere. The volatile products and condensed residues were analyzed. The thermolysis of di(tetrazol-5-yl)amine under controlled conditions was accompanied by the evolution of 2.5 mols of nitrogen. The decomposition of some polymeric and low-molecular tetrazoles under specific conditions led to the sample ignition and formation of nitrogen as the main gaseous product and condensed residues of unusual structure.

#### 11.1.3.2 Thermal Stability and Thermal Decomposition of Tetrazole Derivatives

The mutual interconversion and decomposition reactions of four tetrazole isomers (1*H*-TZ, 2*H*-TZ, 5*H*-TZ, and an *N*-heterocyclic carbene (14*H*)) have been studied theoretically using *ab initio* computational chemistry [738]. Computations allowed resolution of the existing discrepancies in the mechanism and key intermediates of tetrazole thermolysis. The tautomeric equilibria between 1*H*-TZ, 2*H*-TZ, and 14*H* turned out to play a very important role in the mechanism of thermal decomposition. Although the barriers of monomolecular tautomeric transformations were found to be high (209–293 kJ/mol = 50–70 kcal/mol), the concerted double H atom transfer reactions in the H-bonded complexes of tetrazole tautomers have profoundly lower barriers (75.3–117 kJ/mol = 18–28 kcal/mol). For all species considered, the unimolecular reactions of N<sub>2</sub> elimination were predicted to dominate over the elimination of hydrazoic acid. In agreement with existing experimental data, the effective activation energy of thermolysis was calculated to be 151 kJ/mol (36.2 kcal/mol).

#### 11.1.4 Strand Burning of Tetrazoles

The current section deals only with the strand burning of the unsubstituted tetrazole by itself. There are several other sections later in this chapter that discuss strand burning of 5-aminotetrazole and other tetrazole derivatives.

When investigating the burning of pressed mixtures of tetrazole and sodium tetrazolate, an unusual type of self-organization in combustion accompanied by a formation of a peculiar dynamic dissipative structure was observed. When a pressed mixture of tetrazole and sodium tetrazolate burned, both in an inert atmosphere and in air, an incandescent liquid spheroidal reaction zone of definite size was observed. This feature has been described as a liquid flame [739–742]. The flame formed during the combustion of this structure has the appearance of a luminous mobile fluid sphere, as observed by high-speed photography. This flame leads the process and is accompanied by a considerable gas evolution and an intensive dispersion of condensed products [743]. The conductivity in the combustion wave was measured to investigate the morphology of condensed products formed by liquid-flame combustion. The chemical compositions of the gaseous and condensed products of the thermal decomposition and combustion of pure tetrazole, sodium tetrazolate, and a mixture of both of them were studied by  $^1\text{H}$  NMR, IR, mass spectrometry, gas chromatography, elemental analysis, and XRD [744–746]. The porous residue left behind after the tetrazole/sodium tetrazolate combustion is like a “klinker,” which is a desirable residue structure for gas generants in airbag inflators because less dust clogs the filters (which can make people cough when airbags are deployed).

The combustion behavior of tetrazole and 5-chlorotetrazole was studied in the form of pressed strands in a window constant-pressure bomb in the pressure range of 0.1–36 MPa [747]. Temperature profiles in the combustion wave were measured using thin tungsten-rhenium thermocouples embedded in the strands. Analysis of condensed combustion products was carried out using IR spectrophotometry. The principal feature of tetrazole combustion has been shown to consist in the formation of stable energetic nitrile derivatives in the combustion products rather than equilibrium adiabatic composition, resulting in incomplete heat release. Periodic variations in the surface temperature involved a gradual accumulation of a product of high decomposition/boiling temperature at the burning surface, followed by ejecting thereof in the gas and clearing the surface.

The combustion products and temperature distribution in the flame zone of a self-sustained decomposition combustion wave of tetrazole and 5-chlorotetrazole were measured in the absence of air [748, 749]. During the combustion of tetrazole in the absence of an oxidizing agent, non-equilibrium adiabatic combustion products and stable high-energy nitrile derivatives are formed. This prevents the release of all the energy stored in the energetic material. The thermal decomposition takes place at 423–523 K (150–250 °C). The combustion of tetrazole takes place in an unconventional regime that is characterized by a cyclic variation of the surface temperature. This is due to the repeated accumulation of the thermal decomposition products on the sur-

face layer (boiling temperature of the decomposition products is significantly higher than the boiling temperature of the tetrazole), which leads to the subsequent removal of the formed layer and cleaning of the surface.

## 11.2 Tetrazolium and Tetrazolate Salts

Tetrazole is amphoteric and can become protonated when reacted with strong acids.

Tetrazole is a weak acid and has an acidity constant of  $\text{p}K_{\text{a}} = 4.90$  and can act as an acid when reacted with strong bases like BOH, where B is the cation of a strong base [246]:

An excellent summary review of azole (imidazole, triazole, tetrazole) salts with 387 references is given in [109]. Depending on the type of substituent(s) on the two tetrazole rings, energetic salts can be formed in which both the cation and the anion contain a tetrazole ring [750].

### 11.2.1 Tetrazolium Salts

Relatively little work was done on the nitrate or perchlorate salts of the unsubstituted tetrazole. Substantially more work was done on substituted tetrazoles. Substituents on the tetrazole ring can improve the thermal stability and the energy content of these compounds. The most common substituted tetrazole is the 5-aminotetrazole and a substantial amount of work was done on salts derived from 5-aminotetrazole (abbreviated as 5-AT). The physical properties of tetrazolium and substituted tetrazolium salts are summarized in Table 46. The perchlorates are the most stable and the dinitramides are the least stable tetrazolium salts. All are potentially explosive and some are very friction sensitive.

The most facile route for the formation of 1*H*-tetrazole is the reaction of sodium azide with ammonium chloride and orthoethyl formate in glacial acetic acid. 1*H*-Tetrazole was deprotonated using alkali hydroxides or carbonates yielding the corresponding metal salts [753]. The nitrogen-rich salts  $\text{NH}_4\text{TZ} \cdot \text{H}_2\text{O}$  and  $\text{N}_2\text{H}_5\text{TZ}$  were synthesized by the reaction of 1*H*-tetrazole with aqueous  $\text{NH}_3$  and  $\text{N}_2\text{H}_4$  solutions,

**Table 46:** Physical properties of tetrazolium and tetrazolate salts.

|                       | ClO <sub>4</sub> <sup>−</sup>                 | —             | —       | —                         | —   | 1.874                        | +158.3                                      | +37.8    | —                                       | [2]        |

respectively [752]. All compounds were characterized using vibrational (IR and Raman) spectroscopy, multi-nuclear (<sup>1</sup>H, <sup>13</sup>C, <sup>14</sup>N, <sup>15</sup>N) NMR spectroscopy, and elemental analysis. The structures in the crystalline state were determined using low-temperature XRD. The physico-chemical properties of all compounds were investigated using DSC and the HOFs were calculated using heats of combustion obtained by bomb calorimetry. The sensitivities were tested using the BAM drophammer and friction tester. Ammonium tetrazolate crystallizes in monoclinic crystal shapes, space group *P2<sub>1</sub>/n*, with unit cell parameters of *a* = 7.211(1) Å, *b* = 4.0108(8) Å, *c* = 17.991(4) Å, *β* = 91.97(3)°, *V* = 520.0(2) Å<sup>3</sup>, *Z* = 4, *ρ* = 1.343 g/cm<sup>3</sup>. Hydrazinium tetrazolate crystallizes in orthorhombic crystal shapes, space group *Ccca*, with unit cell parameters of *a* = 6.763(1) Å, *b* = 17.7510(4) Å, *c* = 16.3160(8) Å, *V* = 1958.7(3) Å<sup>3</sup>, *Z* = 16, *ρ* = 1.385 g/cm<sup>3</sup>. Tetrazolium dinitromethanide salts can be very insensitive to impact [754].

Properties of methyl-substituted tetrazoles, aminotetrazoles, and quaternary salts were omitted from Table 46 but are available in the literature. Properties of some of the tetrazolium compounds are also found in a separate chapter on ionic liquids in this book.

5-Alkyl-1,2,4-tetrazoles can be quaternized at N4 by reaction with equivalent amounts of alkyl iodides under neat conditions to produce quaternary salts in >98% isolated yields. In this case, 2-amino-1,2,4-tetrazole was readily quaternized at N4 with a concentrated solution of strong acid (nitric or perchloric acid) using methanol as a solvent to form salts in nearly quantitative yields and high purity [404].

The *N*-amino group behaves as an electron-withdrawing group in high-nitrogen heterocycles. Exchanging the position of the amino group from one to four on the

tetrazole ring does affect the physical properties of the resulting salts; e.g., the melting point of the nitrate salt is lowered by 52 °C while having a minimal change in the melting point for the analogous perchlorate (8 °C lower). Concomitantly the thermal stability of the nitrate is improved by 32 °C while that of the perchlorate is lowered by 27 °C. Properties of these triazolium and tetrazolium salts are summarized in Table 47.

The rapid thermal decomposition of substituted tetrazolium salts was analyzed by T-jump/time-of-flight mass spectrometer (TOFMS) capable of high heating rates (up to 10<sup>6</sup> K/s) and rapid sampling. This included 5-amino-1-methyl-1*H*-tetrazolium dinitramide, 1,5-diamino-4-methyl-1*H*-tetrazolium dinitramide, 1,5-diamino-1*H*-tetrazolium nitrate, 1,5-diamino-4-methyl-1*H*-tetrazolium azide, and 5-aminotetrazolium dinitramide [755]. In the area of high-oxygen carriers, complex nitrate anions were successfully combined with tetrazolium cations to yield CO/H<sub>2</sub>O balanced ionic liquids of interest for liquid monopropellants [756].

#### 11.2.1.1 Computational Chemistry for Tetrazolium Salts

Numerous theoretical computational studies have been done for tetrazole and other heterocyclic compounds. In most cases the objective was to obtain more accurate data on the enthalpy of formation of the parent molecule, tetrazole, itself and also of the derivatives obtained by substituting one or more hydrogens with other groups (preferably explosophoric groups). Similar calculations were performed for the tetrazolium and tetrazolate salts. Doing the predictive calculations on a computer was much safer than trying to prepare these sensitive compounds in the laboratory and risking explosions before the compound could be burned in a calorimeter. Other calculations attempted to establish a correlation between the impact sensitivity and the bond energy of the weakest bond in the molecule.

A computational approach to the prediction of the HOFs of solid-state energetic salts from an electronic structure and VBT calculations used as its starting point reliable HOF's for energetic precursor molecules and ions [167]. The  $\Delta H_f^\circ$ 's of more complex energetics species, such as substituted imidazole, 1,2,4-triazole, and tetrazole molecules and ions containing amino, azido, and nitro (including methyl) substituents were calculated using an isodesmic approach at the MP2/complete basis set level. Based on comparisons to experimental data for neutral analogues, this isodesmic approach was accurate to <12 kJ/mol (<3 kcal/mol) for the predicted cation

Data Source: [404].

and anion  $\Delta H_f$ 's. The  $\Delta H_f$ 's of the energetic salts in the solid state were derived from lattice energy (UL) calculations using a VBT approach. Some of the tetrazolium salts are also low-melting ionic liquids.

Energetic heterocyclic compounds derive most of their energy either from oxidation of the carbon backbone as with traditional energetic materials (such as TNT and HMX) or from their high positive HOFs, such as nitrogen-rich compounds, including 3,3'-azobis(6-amino-1,2,4,5-tetrazine) and tetrazole azide.

In trying to synthesize tetrazolium azotetrazolate salts, disodium 5,5'-azotetrazolate pentahydrate was reacted with 1,4-dimethyl-5-aminotetrazolium iodide or 1,5-diamino-4-methyltetrazolium iodide. However, the metathetical reaction of sodium azotetrazolate with tetrazolium iodide at reflux in water yielded only dihydrated species (1,4-dimethyl-5-aminotetrazolium azotetrazolate dihydrate (**1**) or 1,5-diamino-4-methyl-tetrazolium azotetrazolate dihydrate (**3**)) in both instances [740]. The numbers in parentheses refer to the salts listed in Table 48. However, when silver azotetrazolate was used instead of the sodium salt in dry methanol, the anhydrous compounds 1,4-dimethyl-5-aminotetrazolium azotetrazolate (**2**) and 1,5-diamino-4-methyl-tetrazolium azotetrazolate (**4**) formed. All materials were fully characterized using elemental analysis, MS, vibrational (IR, Raman) and NMR ( $^1\text{H}$ ,  $^{13}\text{C}$ ) spectroscopy, DSC, and XRD. Decomposition started at the melting points. The detonation pressures and velocities were calculated from the energies of formation using the EXPLO5 code and are summarized in Table 48. Because these compounds are slightly under-oxidized, their performance can be boosted by adding some oxidizer like AN or ADN. Performance calculations were made for tetrazolium azotetrazolates with ADN, increasing the detonation pressure from 20 to 31 GPa and increasing the detonation velocity from 7800 to 8800 m/s. The impact sensitivity was >30 J and the friction sensitivity was above 360 N. There was no reaction in the ESD test.

DFT and volume-based thermodynamics (VBT) calculations were performed to screen 34 protonated and 34 methylated tetrazolium energetic salts with high energy and good stability [758]. Combinations of tetrazolium cations containing different substituents ( $-\text{CH}_3$ ,  $-\text{NO}_2$ ,  $-\text{NF}_2$ ,  $-\text{CN}$ ,  $-\text{N}_3$ ,  $-\text{NH}_2$ ) with energetic anions ( $\text{NO}_3^-$ ,  $\text{N}(\text{NO}_2)_2^-$ ,  $\text{N}_3^-$ ,  $\text{ClO}_4^-$ ) were made to predict their densities, thermodynamic properties, and explosive performances. The focus was primarily on investigating the role of different substituents and energetic anions in the design of high-energy salts. The volumes of the cations and anions were estimated to obtain the crystal densities of the salts from electronic structure calculations. The HOFs of cations, anions, and lattice energies of the salts were calculated separately to obtain the  $\Delta H_f$ 's of the salts based on Born-Haber energy cycles. Using these densities and HOFs, the detonation velocities and detonation pressures of the salts were predicted by K-J equations. When the H atom of the tetrazolium cation is replaced by  $-\text{CH}_3$ ,  $-\text{CN}$ , or  $-\text{NH}_2$ , the density of its nitrate salt is smaller than that of unsubstituted tetrazolium nitrate. The  $\Delta H_f$ 's of the nitrate salts containing the protonated tetrazolium cations are larger

than those of the nitrate salts containing the methylated tetrazolium cations with the same substituent and substitution position.

#### 11.2.1.2 Tetrazolium Azide

The enthalpy of formation of tetrazolium azide,  $\text{CHN}_7$ , is +458 kJ/mol (+109.5 kcal/mol). It is closely related to 5-azidotetrazole, which is stable at room temperature but is extremely shock and friction sensitive and detonates readily. Tetrazolium azide, a very nitrogen-rich material (88.3% N) with high shock and friction sensitivity, can be prepared in good yield by the diazotation reaction of 5-aminotetrazole, followed by treatment of the formed diazonium salt with sodium azide [759]. Synthesis in diethyl ether/methanol and recrystallization from diethyl ether afforded colorless cubes which formed monoclinic crystals, space group  $P1_21/n1$ , with unit cell parameters of  $a = 1346.6(5)$  pm,  $b = 499.6(2)$  pm,  $c = 1360.9(5)$  pm,  $\beta = 105.14(1)^\circ$ ,  $V = 0.884(2)$  nm<sup>3</sup>,  $Z = 8$ , and  $\rho = 1.670$  g/cm<sup>3</sup>. The observed structural parameters were in good accordance with the results from MO calculations (1 picometer = 1 pm =  $10^{-12}$  m = 0.01 Å; 1 nano-meter = 1 nm = 10 Å). A variety of heterocyclic groups (tetrazolo-pyridines, tetrazolo-pyridazines, tetrazolo-pyrimidines, tetrazolo-azines, tetrazolo-purines, etc.) have been reported to exhibit tetrazole-azide isomerization.

#### 11.2.2 Tetrazolate Salts

Tetrazole and 5-methyltetrazole form salts with quaternary alkylammonium ions. These salts behave as ionic liquids. Several of these ionic liquids were prepared, starting with 5-methyltetrazole and followed by *N,N*-dimethylbutylamine, isopropylamine, diisopropylamine, butylamine, or *n*-pentylamine. These were tested as solvents for AP or potassium perchlorate with a view of using them as monopropellants [184].

When 1-butylamine, 1-pentyl amine, or 1-hexylamine reacted with 5-methyl-1*H*-tetrazole, molten salts were formed. Indeed, the melting point ranges for the [1-butylammonium][5-methyl-1-tetrazolate], [1-pentylammonium][5-methyl-1-tetrazolate], and [1-hexylammonium][5-methyl-1-tetrazolate] were remarkably low at between 235 to 239 K (−38 to −34 °C), 238 to 243 K (−35 to −30 °C), and 235 to 241 K (−38 to −32 °C), respectively. When plotting the melting point versus the alkyl chain length of the primary amines, the shape of the plot is noticeably similar to that demonstrated for imidazolium-based ILs with a minimum of melting point at chain lengths with four to six carbon atoms. The wide range of temperatures at which the alkylammonium 5-methyl-1*H*-tetrazolates are liquids is particularly attractive for rocket propulsion under varied environmental conditions as well as for storage considerations.

Energetic ILs (EILs) can be formed from tetrazolium cations with oxidizing anions (perchlorate, nitrate, dinitramide) or energetic cations with tetrazolide anions [760].

Claimed in this patent are EILs comprising a tetrazolide anion and/or a tetrazolium cation.

Various tetrazolate salts of nitrogen-rich amines have been considered as ionic liquid fuels in combination with HAN as either monopropellants or electrospray colloid working fluids [761–765]. Table 49 is a summary of the properties of tetrazolate salts.

**Table 49:** Properties of tetrazolate salts.

| Fuel #          | Fuel name                                                   | Formula                                        | $\Delta H_f(G)$<br>kJ/mol | Density<br>g/cm <sup>3</sup> | Melting point<br>K |

Data Source: [761].

Propellants **1**, **2**, **8**, and **9** in Table 48 demonstrated storability that is equal to or better than that of hydrazine. The remaining six propellants were not storable propellants and, therefore, they were dropped from further consideration.

A series of nitrogen-rich nitroguanidyl-functionalized tetrazolate salts paired with guanidinium-derivatized and heterocycle-based cations were synthesized. Most exhibited better thermal stability, higher density, and a more positive HOF than their tetrazolate analogues [766].

DFT and VBT calculations have been performed to study the crystal densities, HOFs ( $\Delta H_f$ 's), and energetic properties for a series of ionic salts composed of triamino-

guanidinium or ammonium cations and substituted tetrazolate anions [767]. Substitution with  $-\text{NF}_2$ ,  $-\text{CH}_2\text{NF}_2$ ,  $-\text{CF}_2\text{NF}_2$ , or  $-\text{C}(\text{NO}_2)_2\text{NF}_2$  groups increased the densities of the salts. The densities of the tetrazolate salts were affected not only by different substituents but also by different cations. The  $-\text{CN}$  or  $-\text{N}_3$  groups were effective substituents for increasing the  $\Delta H_f$ 's of the salts. The triaminoguanidinium cation was more effective than the ammonium cation for increasing the  $\Delta H_f$ 's of the tetrazole-based salts. Substitution with  $-\text{NO}_2$ ,  $-\text{NF}_2$ , or  $-\text{C}(\text{NO}_2)_2\text{NF}_2$  groups enhanced the explosive performance of the salts.

While it is relatively easy to prepare alkali metal salts of tetrazole, the reactions forming heavier metal salts are more complex. Many metal salts (in particular their perchlorates) are shock-sensitive.

1*H*-Tetrazole was deprotonated using alkali hydroxides or carbonates. This yielded the corresponding metal salts (Li, Na, K, Rb, and Cs), the crystal structures of which were determined using single-crystal XRD. In addition to this, the compounds were characterized using IR, Raman and NMR spectroscopy, elemental analysis, and DSC [753].

There are many publications on complex transition metal salts with tetrazole ligands in the literature, but most of those investigations were aimed at stab-sensitive primary explosives as replacements for lead azide and lead styphnate. We are not attempting to cover this area in this book and, therefore, have not listed these literature references.

## 12 Neutral Mono-Substituted Tetrazole Derivatives

### 12.1 5-Aminotetrazole

5-Aminotetrazole, also known as  $\text{CH}_3\text{N}_5$ , 2*H*-tetrazol-5-amine, tetrazolyl-5-amine, 1*H*-tetrazol-5-ylamine, 5-amino-1,2,3,4-tetrazole, 5-AT, CAS RN [4418-61-5],  $M = 85.07$  g/mol, is a versatile high-nitrogen compound that is widely used in automobile airbag inflator gas generants. It has a very high nitrogen content (82% N). It is readily available and produced in large quantities. Commercial products are usually sold as the monohydrate, CAS RN [15454-54-3]. 5-Aminotetrazole is amphoteric and can form salts with strong bases as well as strong acids. The  $pK$  of 5-aminotetrazole in  $\text{H}_2\text{O}$  is 1.82.

#### 12.1.1 Preparation of 5-Aminotetrazole

5-Aminotetrazole can be prepared by (1) diazotization of aminoguanidine or (2) by reaction of cyanoguanidine or dicyandiamide with hydrazoic acid. Both methods give good results and yield 5-AT in a sufficiently pure state for any potential use. Method (1) is rapid and safe but the yield is low (about 75%), while method (2) is slow

and the reactant, hydrazoic acid, is highly toxic, dangerous, and explosive but gives a higher overall yield and better product quality. Instead of using free hydrazoic acid, cyanamide or dicyandiamide and an azide salt are reacted to produce 5-AT [768].

5-Aminotetrazole can be produced from dicyandiamide and sodium azide in water with zinc bromide as a catalyst [769]. The effects of the reactant molar ratio, catalyst consumption, temperature, and reaction time were measured. The results revealed that, when the molar ratio of sodium azide to dicyandiamide is 1:1.6 and the catalyst consumption of sodium azide to zinc bromide is 1:0.3, the reaction temperature is 348–358 K (75–85 °C), the reaction time is 5.5 h, and the yield of 5-aminotetrazole can reach 83.6%.

5-Aminotetrazole was synthesized by diazotization of aminoguanidinium nitrate and intra-molecular cyclization under basic conditions [770]. The resulting 5-amino-tetrazole was characterized by IR,  $^{13}\text{C}$  NMR, and MS. A mechanism of the reaction was proposed. The key variables affecting the yield, such as acidity or the basicity of the reaction system, reaction temperature, and time were optimized. The optimized procedures were as follows: pH = 2–3,  $T = 293\text{--}303\text{ K} = 20\text{--}30\text{ }^{\circ}\text{C}$ , and  $t = 0.5\text{ h}$  for diazo-reaction; pH = 8–9,  $T = 358\text{--}363\text{ K} = 85\text{--}90\text{ }^{\circ}\text{C}$ , and  $t = 3.5\text{ h}$  for intra-molecular cycliza-tion. The yield of 5-aminotetrazole could be up to 77%.

1-Aminotetrazole carries the amino group on a nitrogen atom instead of the carbon atom, just as in 5-AT. 1-Aminotetrazole has a chain of five catenated nitrogen atoms and is thermally less stable than 5-AT. A three-step synthesis method of 1-aminotetra-zole by condensation, cyclization, and hydrolysis reactions was studied using ben-zaldehyde, triethyl ortho-formate, and hydrazine hydrate as raw materials [771]. The structures of intermediates and products were characterized using IR, NMR, and ele-mental analysis. The influence of the condensation-reaction temperature and molar ratio of triethyl ortho-formate to benzaldehyde hydrazone in cyclization reaction on reaction yield was investigated. The optimum reaction conditions were defined as fol-lows: a condensation-reaction temperature of 273–278 K (0–5 °C) and the molar ratio (triethyl ortho-formate):(benzaldehyde hydrazone) was 1.8:1. The total yield of the three-step reaction was 49.5% (see also [772, 773]).

### 12.1.2 Physical Properties of 5-Aminotetrazole

5-Aminotetrazole forms colorless crystals that melt at 474–479 K (201–205 °C). The monohydrate, which is the common form of commerce, CAS RN [15454-54-3], melts at 471–474 K (198–204 °C) and the melting results in a loss of water. The vapor pressure of 5-aminotetrazole in the range 383–443 K can be expressed by the equation

$$\ln P = 32.929 - 13540/T$$

where  $P$  is the vapor pressure in Pascal and  $T$  is the temperature in kelvin.

The IR spectra of aminotetrazole are shown in Figures 15 and 16 [774, 775]. The Pristera and Fredericks [774] spectra were taken with a sample of the material sus-

**Figure 15:** Infrared spectrum of 5-aminotetrazole. (Reproduced and modified from [774].)

**Figure 16:** IR Spectrum of 5-aminotetrazole. (Reproduced and modified from [722], with permission from the Levering Estate.)

pended in white mineral oil. The mineral oil absorption was always superimposed on the spectrum of the other compound. The main oil absorption bands have been marked by dotted lines in the figures, while the bands considered to be due to the compound under study have been marked with a small vertical line.

#### 12.1.2.1 Molecular Structure of 5-Aminotetrazole

Powder XRD, Rietveld analysis, and DFT calculations were used to investigate the crystal structure of 5-aminotetrazole [776]. It crystallized in an orthorhombic crystal, space group  $P2_12_12_1$  with a 1*H*-form molecule. The orthorhombic phase was stable up to at least 11.6 GPa.

The tautomerism and intra-molecular hydrogen shifts of 5-amino-tetrazole in the gas phase were studied by MO quantum chemical calculations and the six possible tautomers of 1*H*, 4*H*-5-imino-tetrazole (**1**), 1*H*-5-amino-tetrazole (**2**), 2*H*-5-amino-tetrazole (**3**), 1*H*,2*H*-5-imino-tetrazole (**4**), the meso-ionic form (**5**) and 2*H*,4*H*-5-imino-tetrazole (**6**) were investigated [777]. Among these tautomers, there were 2 amino- forms, 3 imino- forms, and 1 meso-ionic structure form. In all the tautomers, 2-*H* form (**3**) was the energetically preferred one in the gas phase. The energy barriers of amino- → imino-tautomerism reactions required were 59 to 73 kcal/mol in the gas phase.

#### 12.1.2.2 Thermodynamic Properties of 5-Aminotetrazole

The enthalpies of formation for 49 tetrazole derivatives were calculated with a DFT method and designed isodesmic and isogyric reactions [778]. The average absolute deviation for five compounds for which experimental  $\Delta H_f$ 's were available was less than 2 kcal/mol. The calculated  $\Delta H_f$ 's indicated that most neutral 2*H*-isomers are predicted to be more stable than the corresponding 1*H*-isomers, whereas the one-substituted tetrazolate anions are more stable than the corresponding two-substituted ones. Results consistently showed that C-substituted tetrazoles are more stable than the corresponding N-substituted isomers. The enthalpy of formation of 5-aminotetrazole is +585 cal/g = +49.7 kcal/mol = +208 kJ/mol. The density is 0.0596 lb/in.<sup>3</sup> = 1.65 g/cm<sup>3</sup>.

The enthalpy of formation of the homologue 2-methyl-5-aminotetrazole  $C_2H_5N_5$ , is  $+500 \text{ cal/g} = +49.5 \text{ kcal/mol} = +207 \text{ kJ/mol}$ .

### 12.1.3 Chemical Properties of 5-Aminotetrazole

5-Aminotetrazole is amphoteric, a property that enables it to form salts with strong acids such as nitric acid, as well as with strong bases such as potassium hydroxide. Its tautomeric form is a 5-iminotetrazole. 5-Aminotetrazole is a weak acid ( $pK_a \approx 6$ ) [779]. It has often been employed as a cation precursor in the synthesis of energetic salts because it behaves as a weak base with strong inorganic acids ( $pK_a \leq 0$ ) under normal conditions. It can be protonated by perchloric, nitric, sulfuric, picric, and hydrohalic acids (HX, X = Cl, Br, I). Both nitrates and potassium salts are used in airbag inflator gas generant formulations along with the parent compound.

5-Aminotetrazole can be easily deprotonated in an aqueous solution using strong bases (hydrazine, biguanidine, LiOH, and NaOH). Hydrazinium 5-aminotetrazolate, biguanidinium 5-aminotetrazolate, and 1-amino-1,2,4-triazolium 5-aminotetrazolate were synthesized by using this methodology. The reaction of guanidinium,  $K^+$ ,  $Rb^+$ , or  $Cs^+$  carbonates and aminoguanidine bicarbonate with 5-aminotetrazole resulted in the formation of salts with concomitant release of carbon dioxide [753, 780]. Similar reactions of 5-AT with alkaline earth metal carbonates lead to hydrated alkaline earth metal salts of 5-amino-1*H*-tetrazole [781].

### 12.1.4 Thermal Decomposition of 5-Aminotetrazole

As in the case of the unsubstituted tetrazole, the thermolysis of 5-AT may start with the tautomeric imino form, which is more labile. The thermal decomposition of the imino form starts just after the melting stage and results in the evolution of hydrogen azide. An increase in the temperature leads to another pathway of thermal decomposition involving corresponding amino forms, which decompose with the elimination of nitrogen. The apparent activation energies of the thermal decomposition of imino forms are in the range of 180–200 kJ/mol. The thermal decomposition of the unsubstituted tetrazole was already discussed in an earlier section of this book. The thermal decomposition of bi- and multiple-substituted tetrazoles will be described in a section further down in this chapter.

The rapid thermolysis of mono- and di-aminotetrazoles was studied by flash pyrolysis with IR analysis of the decomposition products [782]. The thermal decomposition of 5-AT was studied by TGA, DSC, DTA, and via EGA [783]. Solid products of thermal decomposition were identified by IR. Gaseous products were identified by IR and MS. Theoretical considerations of thermodynamic characteristics and bond energies in the 5-AT tautomeric forms and intermediates have been carried out by a MO-SCF computational method. Based on IR and available literature data, it was shown that dehydrated 5-AT exists mainly in the imino form in the solid state. Thermal treatment leads to increased content of the amino form. The thermal decomposition of

the imino form of 5-AT started just after melting and resulted in hydrogen azide and carbodiimide formation. Linear polymers of carbodiimide and melamine derivatives have been identified in the solid residue. At higher temperatures, decomposition of the amino form of 5-AT leads to the evolution of nitrogen. Apparent activation energies of these routes determined from non-isothermal TGA data were 165 and 135 kJ/mol, respectively.

The thermal decomposition of 1-methyl-5-aminotetrazole and 1,5-diaminotetrazole was investigated using TGA, DSC, and thermal volumetric analysis (TVA) [784]. The solid residues and the high boiling point and gaseous products of the decomposition were collected and identified using IR and MS. Both aminotetrazoles started to decompose just after melting; 1-methyl-5-aminotetrazole at 495 K and 1,5-diaminotetrazole at 460 K. Both 1-methyl-5-aminotetrazole and 1,5-diaminotetrazole, in the solid state (and probably in the melt), co-existed in both amino and imino tautomeric forms. Two competing mechanisms of tetrazole ring-breaking with the elimination of either nitrogen or hydrogen azide were proposed.

The hydrohalide (HCl, HBr, HI) salts of 5-amino-1*H*-tetrazole were flash-pyrolyzed under 0.5 MPa of Ar by T-jump/FTIR spectroscopy, and the gaseous products were determined at 623, 673, and 723 K (350, 400, and 450 °C) [785, 786]. Comparison of the products indicated that two global decomposition pathways exist, two reaction channels which give somewhat different products. The first is the dissociation of the salt to form HX and 5-AT followed by decomposition of neutral 5-AT. The second involves the decomposition of the  $[5\text{-AT}]^+$  ion directly. The ratio of these two channels depends on the compound. The first channel is favored over the second channel in the order  $\text{HCl} > \text{HBr} > \text{HI}$ , which is the trend of the  $\text{p}K_{\text{a}}$  values of these acids. This information enables both the relative ordering of the burning rates as a function of pressure. It also allows the determination of the trend of the pressure dependence of the individual burning rates of these compounds. This provides a better understanding of the global decomposition pathways.

The thermal decomposition of 5-AT, 1-methyl-5-aminotetrazole (MAT), 1,5-diaminotetrazole (DAT), poly-1-vinyl-5-aminotetrazole (PVAT), and the sodium salt of 5-aminotetrazole (SAT) have been studied by TGA, TVA, DSC, DTA, and EGA [787]. The kinetic parameters of the thermal decomposition of aminotetrazoles were calculated either by using the Ozawa method or by the method of invariant kinetic parameters. The gaseous products, volatile condensed products, and solid residues were identified by FTIR and GC/MS. Based on the content of the products of thermal decomposition and the kinetic consideration, a mechanism of thermal decomposition of aminotetrazoles has been proposed. Two routes for splitting the tetrazole ring, which leads either to the elimination of nitrogen or hydrogen azide, were suggested. The contribution of each route is changing upon the advancement of the process. It was assumed that hydrogen azide splits out from the prothotropic forms of the tetrazole ring, which have hydrogen atoms by nitrogens in the ring.

Secondary reactions significantly extend and change the variety of the products of the thermal decomposition of aminotetrazoles.

The pathway and *ab initio* direct kinetics of the decomposition of 5-AT to  $\text{HN}_3$  and  $\text{NH}_2\text{CN}$  was investigated by computational methods [788]. Rate constants were evaluated by conventional transition-state theory and canonical variational transition-state theory with tunneling effect over 300 to 2500 K. The results indicated that the tunneling effect and the variational effect are small for the calculated rate constants. The fitted three-parameter expressions calculated using the two different methods were

$$k(T) = 4.07 \times 10^{11} \times T^{0.84} \times e^{(-24200/T)} \text{ s}^{-1}$$

and

$$k(T) = 2.09 \times 10^{11} \times T^{0.89} \times e^{(-23600/T)} \text{ s}^{-1}.$$

The kinetics of the 5-AT thermal decomposition in the condensed phase at high heating rates ( $>100 \text{ K/s}$ ) was studied by a dynamic mass spectrometric thermal analysis using a molecular beam sampling system and the product composition as a function of time was determined [789]. Two routes of 5-aminotetrazole decomposition can be distinguished, one yielding  $\text{HN}_3$  and  $\text{NH}_2\text{CN}$  (route 1), and the other  $\text{N}_2$  and  $\text{CH}_3\text{N}_3$  (route 2). The activation energy and rate constant of 5-AT decomposition were determined for each route. In all experiments at different heating rates, the  $m/e = 43$  peak ( $\text{HN}_3$ ) had a single maximum coinciding with the first maximum of the  $m/e = 28$  peak intensity. Thus, the experimentally observed stepwise character of the thermal decomposition of 5-AT is due to the decomposition of 5-AT itself at the first stage and reactions involving only secondary products at the second stage. Taking melamine ( $\text{C}_3\text{H}_6\text{N}_6$ ) into account, the overall 5-AT thermal decomposition reaction ( $T = \sim 628 \text{ K} = \sim 355^\circ\text{C}$ , heating rate of  $\sim 135 \text{ K/s}$ ) can be expressed by:

The thermal decomposition of 5-aminotetrazole was studied theoretically using computational techniques [790]. The unimolecular primary decomposition reactions of the three most stable isomers of 5-AT were studied in the gas phase and the melt using a simplified model of the latter. In contrast to all previous publications, a consideration of the bimolecular reactions of 5-AT demonstrated that bimolecular reactions are very important, especially in the condensed phase. It was found that the imino form undergoes fast isomerization to the amino form in the H-bonded dimers and does not participate in the 5-AT thermolysis. On the contrary, amino (and probably the 2H isomer) are the main isomers of 5-AT in the melt and gas phase. The  $\text{N}_2$  elimination reaction was found to be the dominant unimolecular channel of the amino and 2H isomer decomposition in both the gas phase and melt. In agreement with the existing experimental data,  $\text{HN}_3$  elimination dominates for some of the considered complexes. It was concluded that the initial stages of thermolysis of 5-AT

cannot be satisfactorily described by the simple unimolecular reactions proposed in the literature. The solid-state decomposition was found experimentally to be negligible for 5-AT. Thermolysis proceeds in the melt and gas phases.

A specular reflection isopotential method was used to investigate the unimolecular decomposition mechanisms of 5-iminotetrazole, 1*H*-5-aminotetrazole, and 2*H*-5-aminotetrazole [791]. Based upon the predicted relative reaction barriers, the initial gaseous products of 5-iminotetrazole unimolecular decomposition are  $\text{HN}_3$  and  $\text{NH}_2\text{CN}$ . On the other hand, the initial gaseous products of 1*H*-5-aminotetrazole and 2*H*-5-aminotetrazole unimolecular decomposition were predicted to be  $\text{N}_2$  and metastable  $\text{CH}_3\text{N}_3$ . These predicted unimolecular decomposition products and activation barriers were in excellent agreement with thermal decomposition experiments reported by others.

A study of the tautomerization and decomposition channels of aminotetrazoles, mainly 5-aminotetrazole and 1,5-diaminotetrazole, showed that one-substituted-aminotetrazoles, two-substituted-aminotetrazole, and one-substituted-iminotetrazoles are the most common isomers of aminotetrazoles [792]. There are two mechanisms for the decomposition of aminotetrazoles: In the first mechanism, the two bonds of the tetrazole ring break off, resulting in  $\text{RN}_3$  and  $\text{NH}_2\text{CN}$ . The second decomposition channel comprises of two steps: Firstly the N—N bond is cleaved, leading to  $\text{RN}_3$ . Then the produced  $\text{RN}_3$  loses one molecule  $\text{N}_2$ . The tautomerization mechanisms of aminotetrazoles represented by 5-aminotetrazole and 1,5-diaminotetrazole were investigated by using high-level quantum chemistry calculations. The results showed that the active energy of the first decomposition pathway is lower than that of other paths. Therefore, it is the most probable reaction path.

Adding one or two methyl groups on the ring to 5-AT results in tetrazoles with slightly different properties. 1-Methyl-5-amino-1*H*-tetrazole,  $\text{C}_2\text{H}_5\text{N}_5$ ; 1*H*-Tetrazol-5-amine, 1-methyl-; CAS RN [5422-44-6] can form salts similar to 5-AT.

5-Aminotetrazole, which is a primary amine with an  $-\text{NH}_2$  group, is one of the most widely used heterocyclic gas generant constituents. Similar properties can be achieved from salts of a secondary amine,  $\text{R}_2\text{NH}$ , which was bis(1*H*-tetrazolyl)amine, *N*-(5*H*-tetrazol-5-yl)-1*H*-tetrazol-5-amine, (also abbreviated as BTA) in this case. It is also amphoteric like 5-AT itself, forming salts with strong bases.

Bis(1*H*-tetrazolyl)amine

The burning rate of the ammonium salt of bis(1*H*-tetrazolyl)amine has been tested as a gas generant ingredient. The burning rate of bis(1*H*-tetrazolyl) amine ammonium

salt and potassium nitrate phase-stabilized AN mixtures; this was examined and an equation for the burning rate as a function of pressure and temperature was obtained [793]. The burning rates predicted by the regression equations were in good agreement with the observed values. The temperature sensitivities were also predicted using the regression equation and compared with the observed values. Good agreement was found between the predicted and observed values.

## 12.2 *N*-Substituted 5-Aminotetrazoles

*N*-Substituted aminotetrazoles can be obtained by reaction of cyanogen azide with primary amines [794] or with secondary amines [795]. During the reaction, traces of moisture resulted in the formation of a byproduct sodium 5-azidotetrazolate, which was subsequently isolated and removed as a highly explosive and shock-sensitive solid. Tetrazoles synthesized from secondary amines included 5-dimethylaminotetrazole, 5-diethylaminotetrazole, 5-(pyrrolidin-1-yl)-1*H*-tetrazole, 5-(piperidin-1-yl)-1*H*-tetrazole, 1,4-bis(1*H*-tetrazol-5-yl)piperazine, 5-(morpholin-4-yl)-1*H*-tetrazole, and several similar tetrazole derivatives [796].

## 12.3 Other Mono-Substituted Tetrazole Compounds

Tetrazole can be linked to a nitroguanidine group, giving *N*-nitro-*N'*-1*H*-tetrazol-5-yl-guanidine, also known as tetrazol-5-yl-*N*-nitroguanidine, *N*-(5-tetrazolyl)-nitroguanidine; Guanidine, *N*-nitro-*N'*-1*H*-tetrazol-5-yl;  $C_2H_4N_8O_2$ , AT-NQ,  $M = 172.11$  g/mol, CAS RN [92260-29-2]. It decomposes at 513–518 K (240–245 °C). There are two tautomeric forms possible for this molecule but structure (I) is more likely than structure (II) because the conjugated N=C double bond is in resonance with the aromatic system in the ring. Another possibility would be a zwitterionic structure.

This is a weak acid and forms a guanidinium salt and a potassium salt. The guanidinium salt of *N*-nitro-*N'*-1*H*-tetrazol-5-yl-guanidine,  $C_3H_5N_8O_2$ ,  $M = 189.16$  g/mol, has been prepared and patented as an additive to double-base propellants [797]. It melts at 509–513 K (236–240 °C).

1-(Tetrazol-5-yl)-2-nitroguanidine and 1-nitroguanyl-1,2,4-triazole were synthesized by reaction of 1-nitro-2-methylisothiurea with amino heterocycles (5-aminotetrazole, 3,5-diamino-1,2,4-triazole, and 5-amino-1,2,4-triazole) [798]. 1,2,4-Triazolyl and tetrazolyl derivatives of nitroguanidine were investigated by  $^1\text{H}$ ,  $^{13}\text{C}$ , and  $^{15}\text{N}$ -NMR spectroscopy. NMR data showed that a product of the reaction between 1-nitro-2-methylisothiurea and 5-amino-1,2,4-triazole is not 1-nitroguanyl-3(5)-amino-1,2,4-triazole, as was assumed previously. It was 1-(1,2,4-triazol-3(5)-yl)-2-nitroguanidine instead. Based on NMR data, the most prevalent structures are the 1,2,4-triazole- and tetrazole-type structures; other possible structures imply an imine form [799].

## 12.4 Nitro- and Nitramino-Tetrazole Derivatives

### 12.4.1 1-Nitrotetrazole and 5-Nitrotetrazole

The enthalpy of formation ( $\Delta H_f^\circ$ ) in the gas phase of 1-nitrotetrazole was theoretically investigated by employing DFT and isodesmic reactions [156]. A correlation was developed between impact sensitivity h50% and the defined sensitivity index. Based on this empirical relationship and its extrapolation, the impact sensitivities of compounds, for which experiments were not available, were extrapolated. 1-Nitrotetrazole is a nitramine while 5-nitrotetrazole, CAS RN [55011-46-6], is a C—NO<sub>2</sub> nitro compound.

1-Nitrotetrazole    5-Nitrotetrazole

Both 4,5-dinitroimidazole and 5-nitrotetrazole, with electron-withdrawing nitro-substituents on the ring, are strong NH acids ( $\text{pK}_a = 0.8$  for 5-nitro-tetrazole). 5-Nitro-2*H*-tetrazole (**1**), 1-methyl-5-nitrotetrazole (**2**), and 2-methyl-5-nitrotetrazole (**3**) were synthesized, starting from the corresponding 5-amino-substituted tetrazoles [800]. The compounds were characterized by analytical and spectroscopic methods and their solid-state structures were determined by low-temperature XRD. Computational methods were used to estimate the energies of formation ( $\Delta U_f^\circ$ ) of the molecules, which are highly endothermic and were calculated as follows: (**1**) 2527 kJ/kg, (**2**) 2253 kJ/kg, and (**3**) 2006 kJ/kg. Calculated detonation velocities ( $V_{\text{det}}$ ) and detonation pressures ( $P_{\text{det}}$ ) were (**1**)  $V_{\text{det}} = 9457 \text{ m/s}$  and  $P_{\text{det}} = 390 \text{ kbar}$ , (**2**)  $V_{\text{det}} = 8085 \text{ m/s}$  and  $P_{\text{det}} = 257 \text{ kbar}$ , and (**3**)  $V_{\text{det}} = 8109 \text{ m/s}$  and  $P_{\text{det}} = 262 \text{ kbar}$ . These performances are comparable to commonly used secondary explosives (e.g., RDX). All three neutral compounds could be easily initiated by impact (<2J) and with

high detonation velocities. Excellent combined oxygen and nitrogen contents offer a more powerful and environmentally friendly alternative to commonly used primary explosives in initiating devices.

DFT computations were used to study the HOFs, electronic structure, energetic properties, and the pyrolysis mechanism of a series of trinitromethyl-substituted heterocycles, including triazole, tetrazole, furazan, tetrazine, and fused heterocycles [726]. It was found that tetrazine and tetrazole are effective structural units for increasing the  $\Delta H_f$ 's of the derivatives. The substitution of hydrogen by a combination of nitro and trinitromethyl groups is very useful for improving their  $\Delta H_f$ 's. The calculated energetic properties indicated that the combination of the nitro and trinitromethyl groups is very helpful for improving detonation properties and oxygen balances (OB).

The DFT method was used to study the HOFs, energetic properties, and thermal stability for a series of trinitromethyl-substituted tetrazole derivatives with different substituents [801]. It was found that the  $-\text{NO}_2$ ,  $-\text{NHNO}_2$ , or  $-\text{NF}_2$  groups play a very important role in increasing the HOFs of the derivatives. The calculated detonation velocities and pressures indicated that the group  $-\text{CF}_2\text{NF}_2$ ,  $-\text{NHNO}_2$ ,  $-1H$ -tetrazolyl,  $-2H$ -tetrazolyl, or  $-1,2,4,5$ -tetrazinyl are effective structural units for enhancing the detonation performance of the rings they are attached to. An analysis of the BDE for several relatively weak bonds indicated that incorporating the  $-\text{NHNO}_2$  and  $-\text{NH}_2$  group into the parent ring decreased their thermal stability. Considering the detonation performance and thermal stability, 37 compounds in this study could be viewed as potential high-energy compounds. Their OB were close to zero.

Sodium 5-nitrotetrazolate is a useful intermediate in the synthesis of primary explosives. To minimize the accumulation of hazardous materials in one location, sodium 5-nitrotetrazolate can be prepared by a flow method in a micro-reactor [802]. The sodium salt of 5-nitrotetrazolate can be prepared by reacting aqueous solutions of 5-aminotetrazole (an acid) and sodium nitrite in a continuous flow system at ambient temperature [803], or in a batch process at or above 338 K (65 °C) [804].

Free nitrotetrazole is extremely sensitive but the salts are more stable. 5-Nitrotetrazole is an acid that can form salts with ammonia and alkali metal hydroxides. These salts are suitable as energetic materials in rocket propellants, gas generants, and explosives. Ammonium 5-nitrotetrazolate is usually prepared as the hemihydrate or kept in solution. It can be used as the starting material for the synthesis of other 5-nitrotetrazolate salts of hydrazinium, guanidinium, aminoguanidinium, or even triaminoguanidinium cations. High-nitrogen content energetic salts of ammonium, hydrazinium, guanidinium, aminoguanidinium, diamino-guanidinium, and triaminoguanidinium with 5-nitro- $2H$ -tetrazolate anions were synthesized and characterized (also in form of their hydrates), as detailed in Table 50 from Reference [805].

Metal salts of the 5-nitrotetrazolate anion with alkali metal cations,  $\text{Li}^+$  (**1**),  $\text{Na}^+$  (**2**),  $\text{K}^+$  (**3**),  $\text{Rb}^+$  (**4**), and  $\text{Cs}^+$  (**5**), were synthesized either by the digestion of

**Table 50:** Properties of 5-nitro-2*H*-tetrazolate salts.

Data source: [805].

an acid copper salt of 5-nitrotetrazole with a metal hydroxide or by reaction of ammonium 5-nitrotetrazolate with a suitable metal base (MOH, MHCO<sub>3</sub>, or M<sub>2</sub>CO<sub>3</sub>) in aqueous or alcoholic solution [806]. The compounds were characterized by analytical methods (elemental analysis and mass spectrometry) and spectroscopic methods (NMR and vibrational spectroscopy). The lighter metal salts (**1**) and (**2**), incorporated three and two crystal water molecules in the hydrate sphere, respectively, whereas the heavier alkali metal derivatives formed anhydrous species, and thus showed enhanced sensitivity to friction and shock. The crystal structure of each of the new materials was determined by XRD: (**1**) and (**3**) were monoclinic, *P*2<sub>1</sub>/*c*; (**2**) was triclinic, *P* $\bar{1}$ ; (**4**) was monoclinic, *Cc*; (**5**) was monoclinic, *C*2/*c*. The thermal stability of compounds 1–5 was assessed by DSC measurements and showed significant thermal stability. The energies of combustion of (**1**) and (**2**) were measured in an oxygen bomb calorimeter and found to be 1340(15) cal/g (**1**) and 1200(20) cal/g (**2**). This was used to calculate their standard molar HOFs, which were found to be −610 kJ/mol (**1**) and −360 kJ/mol (**2**).

An improved procedure for the synthesis of ammonium 5-nitrotetrazolate allowed the preparation of the material on a larger scale [807]. Ammonium 5-nitrotetrazolate was selectively alkylated with bromoacetonitrile, yielding 5-nitrotetrazol-2-ylacetoneitrile. A 1,3-dipolar cycloaddition of azide ion to 5-nitrotetrazol-2-ylacetoneitrile resulted in 5-(5-nitrotetrazol-2-ylmethyl) tetrazole, which was used to synthesize energetic salts with ammonium, guanidinium, and aminoguanidinium cations. All compounds were characterized by analytical (elemental analysis and mass spectrometry) and spectroscopic methods (IR, Raman, and NMR spectroscopy), and the crystal structures were determined by low-temperature XRD. The sensitivities and energetic properties of all compounds were determined.

Properties of three nitrogen base salts of 5-nitrotetrazole, ethylenediammonium(1+) 5-nitrotetrazolate, guanidinium 5-nitrotetrazolate, and triaminoguanidinium 5-nitrotetrazolate have been assembled in Table 38 along with properties of seven salts of 1-hydro-3-nitro-1,2,4-triazol-5-one (NTO) [547, 548, 551].

In 2013, a safety property classification and military ordnance qualification was completed for a new primary explosive consisting of copper(I) 5-nitrotetrazolate (also referred to as DBX-1) [808]. This primary stab-sensitive explosive is an environmentally friendly replacement material for lead azide. This is the first primary explosive that has been qualified by the US Navy in over 90 years. The introduction of DBX-1 will eliminate lead from various applications while ensuring all platform requirements are achieved, thus utilizing a green energetic material.

A DFT computational method was used to calculate the optimized geometries, IR spectra, and thermodynamic properties of seven nitrotetrazoles [809]. Their HOFs were computed accurately using designed isodesmic and isogyric reactions. The calculated total energies and HOFs consistently showed that C-nitrotetrazoles were more stable than the N-isomers.

2-Methyl-5-nitrotetrazole was tested as an additive to AN for an AN linear burning rate study and compared to GAP and TNT (Sinditskii et al. 2005). 2-Methyl-5-nitrotetrazole in the form of white plate-like crystals, with a density of 1.64 g/cm<sup>3</sup> and a melting point of 359 K = 86 °C, can be prepared by methylation of 5-nitrotetrazole [810]. Alkylation of 5-AT does not alkylate the amino group but methyl groups go into both the 1- and the 2-position. With diethyl sulfate, only one alkyl group is used, whereas with dimethyl sulfate, both alkyl groups are used.

5-Nitrotetrazole is very hygroscopic. In the TGA the loss of mass at 388–393 K (115–120 °C) was 75%. The detonation velocity was 8.5 km/s (at a packing density of 1.7 kg/m<sup>3</sup>) [811, 812].

#### 12.4.2 5-Nitramino-1*H*-tetrazole

5-Nitramino-1*H*-tetrazole, also known as 5-nitroamino-1*H*-tetrazole; 2*H*-tetrazol-5-amine, *N*-nitro-; is a 5-AT derivative with more acidic properties than 5-AT due to the electron-sucking property of the nitro group on the –NH<sub>2</sub> group. It forms salts with many bases such as the ammonium salt CH<sub>2</sub>N<sub>6</sub>O<sub>2</sub>•H<sub>3</sub>N, CAS RN [57877-65-3].

Three 5-nitraminotetrazole (NATZ) high-nitrogen energetic salts, (ethylene diamine)<sup>+</sup>(NATZ)<sup>–</sup>, (NH<sub>2</sub>NH<sub>2</sub>)<sup>+</sup>(NATZ)<sup>–</sup>•0.5H<sub>2</sub>O, and (carbohydrazide)<sup>+</sup>(NATZ)<sup>–</sup>, were synthesized and characterized by elemental analysis, IR spectra, DSC, TGA-DTG, and single-crystal XRD [813]. The results showed that the crystal belongs to a monoclinic system with space group *Pn*, and unit cell parameters of *a* = 0.37389(1) nm, *b* = 1.2396(5) nm, *c* = 0.8699(4) nm, *β* = 92.212(7)°, *V* = 0.4029 nm<sup>3</sup>; *ρ* = 1.815 g/cm<sup>3</sup>, and *Z* = 2. At a heating rate of 10 K/min., the thermal decomposition process of (NH<sub>2</sub>NH<sub>2</sub>)<sup>+</sup>(NATZ)<sup>–</sup>•0.5H<sub>2</sub>O consisted of one endothermic peak without residues, while the others consisted of one endothermic peak and one exothermic peak.

**Figure 17:** IR Spectrum of 5-nitroaminotetrazole. (Reproduced and modified from [722], with permission from the Levering Estate.)

The salts of 5-nitroaminotetrazole absorb in the region of 6.4 to 6.47 microns. The free acid, 5-nitroaminotetrazole, absorbs at 6.18 microns (Figure 17).

5-Nitroaminotetrazole is a dibasic acid; the anion may have structure I or II in its monobasic salts.

5-Nitroaminotetrazole

Only structure II, which represents an increased conjugation in the salt form over the free acid, can explain the shift away from the visible region. Based on this IR absorption data the “aci-nitro form,” represented by structure II is more likely for the monobasic salt structure of 5-nitroaminotetrazole. The publication [775] contains IR spectra of the potassium, di(ethylammonium), and anilinium salts of 5-nitroaminotetrazole.

Diammonium 5-nitraminotetrazolate melts at 493–494 K (220–221°C) and diguanidinium 5-nitraminotetrazolate melts at 498–499 K (225–226°C). The HOF of ammonium 5-nitraminotetrazolate,  $C_1N_7H_5O_2$ ,  $M = 147.1$ , is  $+222 \text{ cal/g} = +32.66 \text{ kcal/mol} = +136.6 \text{ kJ/mol}$  and the density is  $0.0538 \text{ lb/in.}^3 = 1.49 \text{ g/cm}^3$  [61].

Rapid thermal decomposition of nitraminotetrazole and nitraminotriazole was followed by instant IR analysis of the decomposition products to identify the weak link (“trigger linkage”) where the decomposition starts [814–816]. 5-Nitroaminotetrazole forms energetic salts with several bases [577].

## 12.5 5-Nitrimino-1*H*-tetrazole

Nitrimino compounds contain substituted =NH groups instead of —NH<sub>2</sub> groups (just as in amino compounds). Rather than introducing a nitro group to the ring, treating 5-AT with fuming nitric acid results in the formation of 5-nitriminotetrazole. The nitration of 5-amino-1*H*-tetrazole, 5-amino-1-methyl-1*H*-tetrazole, or 5-amino-2-methyl-2*H*-tetrazole with HNO<sub>3</sub> (100%) gave 5-(nitrimino)-1*H*-tetrazole, CAS RN [18588-16-4], 1-methyl-5-(nitrimino)-1*H*-tetrazole, or 2-methyl-5-(nitramino)-2*H*-tetrazole [817]. These energetic compounds were characterized using IR, Raman, multi-nuclear (<sup>1</sup>H, <sup>13</sup>C, <sup>14</sup>N, and <sup>15</sup>N) NMR, MS, XRD, DSC, bomb calorimetry, and elemental analysis. The thermal decompositions were investigated by gas-phase IR as well as DSC. The heats of explosion, detonation pressures, and detonation velocities were calculated, revealing that the calculated performance values were similar to those of common explosives such as TNT and RDX. Sensitivity testing by BAM methods (drophammer and friction) revealed that the materials were too sensitive for a LOVA propellant.

Similarly, nitration of 1-methyl-5-aminotetrazole results in the formation of 1-methyl-5-nitriminotetrazole. Both compounds, 5-nitriminotetrazole and 1-methyl-5-nitriminotetrazole, are acidic and can form salts with many nitrogen-rich cations including carbohydrazide [818]. Diaminouronium 5-nitriminotetrazolate crystallizes in the monoclinic chiral space group *Pn*. Its density of 1.806 g/cm<sup>3</sup> (calculated using XRD) is quite high in comparison with other tetrazolate salts, whereas its 1-methyl homolog has a density of only 1.585 g/cm<sup>3</sup>. The physical properties of diaminouronium 5-nitriminotetrazolate are listed in Table 51. Sensitivity tests with diaminouronium 5-nitriminotetrazolate produced the results listed in Table 52.

Nitriminotetrazole can also be obtained by the diazotization of nitroaminoguanidine to nitroguanylazide and subsequent ring formation under alkaline conditions. Nitriminotetrazole, CH<sub>2</sub>N<sub>6</sub>O<sub>2</sub>, CAS RN [18588-16-4], has a molecular mass of 130.066 g/mol, an oxygen balance of −12.3%, forms monoclinic crystals with space group *P2<sub>1</sub>/c* (No. 14) with *a* = 9.4010(3) Å, *b* = 5.4918(1) Å, *c* = 9.3150(3) Å, *α* = 90°, *β* = 105.762(3)°, *γ* = 90°, *V* = 462.84(2) Å<sup>3</sup>, *Z* = 4, and has a density of 1.87 g/cm<sup>3</sup>. It also has a predicted detonation pressure of 363 kbar, and a predicted detonation velocity of 9173 m/s, which is higher than that of TNT (*P* = 202 kbar, *v*<sub>Det</sub> = 7150 m/s). The enthalpy of formation was calculated from the heat of combustion determined in a calorimeter bomb and found to be +264 kJ/mol. In the DSC, nitriminotetrazole showed a very low

**Table 51:** Solid-state properties of diaminouronium 5-nitriminotetrazolate.

Data source: [818].

decomposition point at 395 K (122°C). The heat of decomposition  $\Delta H_{\text{dec}}$  was 2638 J/g. Nitriminotetrazole is very sensitive towards impact (<1.5 J) and friction (<8 N). Since the value is comparable with lead azide, it should be considered to be a primary explosive and, therefore, should only be handled with appropriate precautions [819]. The rapid thermal decomposition of 5-nitriminotetrazole on a heated platinum filament has been observed with a Raman spectrometer and intermediate species formed during its decomposition could be identified [704].

1-Methyl-5-nitriminotetrazole and 2-methyl-5-nitraminotetrazole, which were obtained by the nitration of 1-methyl-5-aminotetrazole or 2-methyl-5-aminotetrazole, were deprotonated using an aqueous ammonia solution yielding the energetic compounds ammonium 1-methyl-5-nitriminotetrazolate and ammonium 2-methyl-5-nitriminotetrazolate [819–821]. The TAG salt of this tetrazole is described in a section dedicated to TAG salts in *Encyclopedia of Liquid Fuels* (chapter “Amides and Imides,” Section 14.6.3).

The properties of the parent nitrimines 1-methyl-5-nitriminotetrazole (**1**) and 2-methyl-5-nitraminotetrazole (**2**) were: (**1**)  $\text{C}_2\text{H}_4\text{N}_6\text{O}_2$ , molecular mass 144.11 g/mol, orthorhombic crystals, space group  $P2_12_12_1$  (No. 19),  $a = 6.6140(1) \text{ \AA}$ ,  $b = 8.5672(2) \text{ \AA}$ ,  $c = 19.2473(4) \text{ \AA}$ ,  $\alpha = \beta = \gamma = 90^\circ$ ,  $V = 1090.62(4) \text{ \AA}^3$ ,  $Z = 8$ , and  $\rho = 1.755 \text{ g/cm}^3$ ; and (**2**)  $\text{C}_2\text{H}_4\text{N}_6\text{O}_2$ , molecular mass 144.11 g/mol, monoclinic crystals, space group  $P2_1/c$  (No. 14),  $a = 9.5278(9) \text{ \AA}$ ,  $b = 7.7308(7) \text{ \AA}$ ,  $c = 8.4598(9) \text{ \AA}$ ,  $\alpha = 90^\circ$ ,  $\beta = 112.875(9)^\circ$ ,  $\gamma =$

90°,  $V = 574.1(1) \text{ \AA}^3$ ,  $Z = 4$ , and  $\rho = 1.667 \text{ g/cm}^3$ . The nitrogen-rich salts were tested and characterized using IR, Raman, multi-nuclear ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ , and  $^{15}\text{N}$ ) NMR spectroscopy, and elemental analysis. The molecular structures in the crystalline state were determined using low-temperature single-crystal XRD. The thermal behavior and the decomposition products were investigated using DSC and IR spectroscopy for the analysis of the off-gassing. The HOFs were calculated using bomb calorimetric measurements of the heat of combustion. The relevant detonation parameters outperformed the values of TNT. The sensitivities were determined using BAM methods, which showed moderate values against impact and friction (drop-hammer and friction tester). Long-term stabilities were also tested. XRD crystallography of the aminoguanidinium salts gave: monoclinic  $P2_1/c$ ,  $a = 370.06(2) \text{ pm}$ ,  $b = 2079.06(9) \text{ pm}$ ,  $c = 859.69(5) \text{ pm}$ ,  $\beta = 99.120(5)^\circ$ ,  $V = 65306(6) \text{ pm}^3$ ,  $Z = 4$ , and  $\rho_{\text{calc}} = 1.639 \text{ g/cm}^3$ . The diaminoguanidinium salt gave: monoclinic  $P2_1$ ,  $a = 365.39(2) \text{ pm}$ ,  $b = 788.82(5) \text{ pm}$ ,  $c = 1124.95(7) \text{ pm}$ ,  $\beta = 91.818(6)$ ,  $V = 32408(3) \text{ pm}^3$ ,  $Z = 2$ , and  $\rho_{\text{calc}} = 1.651 \text{ g/cm}^3$ .

Syntheses of salts with 3-nitroiminotriazolate and 5-nitroiminotetrazolate as anions yielded nitro-containing energetic salts that were thermally stable to  $>473 \text{ K}$  ( $>200^\circ\text{C}$ ) (measured by TGA) [822]. Di(aminoguanidinium) 5-nitroiminotetrazolate crystallized in the monoclinic space group  $P2_1/c$  with an essentially planar 5-nitroiminotetrazolate dianion. Based on experimental and calculated densities and theoretical calculations, all of the salts had calculated detonation pressures and velocities that exceeded those of TNT and a few had values that approached those of TATB.

Alkylation of 5-AT with 2-chloroethanol leads to a mixture of the N-1 and N-2 isomers of (2-hydroxyethyl)-5-aminotetrazole [823]. Treatment of 1-(2-hydroxyethyl)-5-aminotetrazole (**2**) with  $\text{SOCl}_2$  yielded 1-(2-chloroethyl)-5-aminotetrazole (**3**). 1-(2-Azidoethyl)-5-aminotetrazole (**4**) was generated by the reaction of (**3**) with sodium azide. Nitration of (**2**), (**3**), and (**4**) with  $\text{HNO}_3$  (100%) yielded in the case of **2** and **3** 1-(2-hydroxyethyl)-5-nitriminotetrazole (**5**) and 1-(2-chloroethyl)-5-nitriminotetrazole (**6**). Other compounds described were 1-(2-nitratoethyl)-5-nitriminotetrazole monohydrate, 1-(2-Azidoethyl)-5-nitriminotetrazole, potassium 1-(2-azidoethyl)-5-nitriminotetrazolate, sodium 1-(2-chloroethyl)-5-nitriminotetrazolate, ammonium 1-(2-chloroethyl)-5-nitriminotetrazolate, 1-(2-hydroxyethyl)-5-aminotetrazolium nitrate, 1-(2-azidoethyl)-5-aminotetrazolium nitrate, 1-(2-azidoethyl)-5-aminotetrazolium perchlorate monohydrate, and various copper complexes with these compounds. All compounds were characterized by low-temperature single-crystal XRD, IR, Raman and NMR spectroscopy, elemental analysis, MS, and DSC. The HOFs of selected compounds were computed by using heats of combustion obtained by bomb calorimetry or calculated by the atomization method. With these values and the densities determined from XRD, several detonation parameters were calculated using the EXPLO5 program. Also, the sensitivities towards impact and friction were determined using a BAM drop-hammer and a friction tester.

The reactions of 5-nitriminotetrazole with 1-methyl-5-aminotetrazole as well as 2-methyl-5-aminotetrazole were investigated [824]. In the first reaction, 1-methyl-5-aminotetrazole was protonated, yielding 1-methyl-5-aminotetrazolium 5-nitrimino-1*H*-tetrazolate monohydrate. In the latter case, no protonation could be observed and only a co-crystallization of unreacted 5-nitraminotetrazole and 2-methyl-5-aminotetrazole was obtained. Products were characterized by low-temperature single-crystal XRD, IR, Raman and NMR spectroscopy, elemental analysis, as well as DSC. The HOFs were calculated from experimentally obtained heats of combustion. Using these and the X-ray densities, several detonation parameters were computed using EXPLO5 software. The sensitivities towards impact, friction, and electrostatic discharge were determined.

Starting with the alkylation of 5-aminotetrazole and going through several intermediate steps, 1-(2-nitratoethyl)-5-nitriminotetrazole monohydrate and 1-(2-azidoethyl)-5-nitriminotetrazole was synthesized and characterized [823]. Several 5-nitriminotetrazoles and 5-nitraminotetrazoles with 2-nitro-2-azapropyl substitution in the 1-position were synthesized and characterized as energetic materials [825]. HEDMs with ethylene- and propylene-bis(5-nitroiminotetrazolate) as the anions were synthesized and characterized by IR, NMR, elemental analyses, and density [826].

The HOFs and the predicted detonation pressures and velocities were calculated. By using the experimental values for the densities of the nitroiminotetrazolate salts, the detonation pressures and velocities were calculated using Cheetah 5.0. The dihydrazinium salt of 1,2-di(5-nitriminotetrazolo)ethane has a density of 1.733 g/cm<sup>3</sup>, an enthalpy of formation of +1067 kJ/mol, a predicted detonation pressure of 35.27 GPa, and a predicted detonation velocity of 9478 m/s. The oxygen balance is -50.2%.

Bishydrazinium salt of 1,2-di(5-nitriminotetrazolo)ethane

Mono-, di-, and tri-substituted nitroiminotetrazoles can be synthesized from aminotetrazoles (obtained from the reaction of cyanogen azide with primary amines) by treatment with 100% nitric acid and were characterized by spectroscopic methods, elemental analysis, and (in some cases) XRD [827, 828]. The HOFs of these energetic materials were calculated as were their detonation pressures and velocities.

Hydrazinium 5-nitrimino-1H-tetrazolate and dihydrazinium nitriminotetrazolate monohydrate were synthesized by the reaction of hydrazine with 5-nitriminotetrazole [829]. The salts were characterized by single-crystal XRD, NMR, IR and Raman spectroscopy, and DSC. The sensitivities towards impact, friction, and electrical discharge were determined. Several detonation parameters (e.g., the heat of explosion, detonation velocity) were computed by using the EXPL05 computer code based on calculated HOFs and X-ray densities.

The hydroxylammonium salts of monodeprotonated 5-nitriminotetrazole, double deprotonated 5-nitriminotetrazole, 1-methyl-5-nitriminotetrazole, and 2-methyl-5-nitraminotetrazole were prepared from the corresponding 5-nitriminotetrazoles as free acids and an aqueous solution of hydroxylamine or the metathesis reactions of hydroxylammonium hydrochloride with the silver salt of the corresponding nitriminotetrazole, respectively [830]. The energetic salts were characterized by single-crystal XRD, NMR, IR and Raman spectroscopy, as well as DSC. The sensitivities towards impact, friction, and electrical discharge were determined. Several detonation parameters (e.g., the heat of explosion, detonation velocity) were computed by using the EXPL05.04 computer code based on calculated HOFs and X-ray densities.

The structural and chemical properties of triaminoguanidinium 1-methyl-5-nitriminotetrazolate  $\text{C}_3\text{H}_{12}\text{N}_{12}\text{O}_2$  have been investigated at room pressure and under high-

pressure isothermal compression using XRD, and Raman and IR spectroscopy [831]. The shock sensitivity of energetic materials depends on the behavior of these materials upon sudden compression. Some undergo phase changes at high pressures. There was a reversible martensitic structural transformation to a new crystalline phase. Beyond 15 GPa, pressurization induced irreversible chemical reactions.

## 13 Mono-Substituted Tetrazolium and Tetrazolate Salts

### 13.1 5-Aminotetrazolium Nitrate

5-Aminotetrazolium nitrate, also known as  $C_1H_4N_6O_3$ ,  $CH_3N_5 \bullet HNO_3$ ,  $[CH_4N_5]^+ [NO_3]^-$ , 5-aminotetrazole nitrate, 2*H*-tetrazol-5-amine, nitrate (1:1), 5-ATN, CAS RN [43146-62-9],  $M = 148.081$  g/mol, is a very useful propellant ingredient with high nitrogen content (56.75% N) and good oxygen balance (−10.8%). 5-ATN and oxidizing potassium salts are sometimes used in gas generant formulations along with the parent compound 5-AT.

The oxygen balance of 5-aminotetrazolium nitrate is −10.8%%. As such, it does not require much additional oxidizer for self-deflagration. 5-Aminotetrazolium nitrate melts and decomposes explosively once it reaches 447–448 K (174–175 °C). The enthalpy of formation of 5-aminotetrazolium nitrate is +130 cal/g = +19.25 kcal/mol = +80.5 kJ/mol.

The combustion behavior of salts of 5-aminotetrazole with inorganic acids (HCl, HBr, HI, HNO<sub>3</sub>, HClO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>) and picric acid was investigated at 0.1–40 MPa in a windowed constant-pressure bomb [832]. Preliminary IR-spectrometry analyses of the salts pointed to the protonation of a nitrogen atom on the tetrazole ring. The temperature distribution in the combustion wave was measured with thin tungsten-rhenium micro-thermocouples. The salts of 5-AT with inorganic non-oxidizing acids all had higher burning rates than 5-AT itself despite the decrease in their energetic properties, which occurred due to salt formation. The stronger the acid, the higher the burning rate became.

For the preparation of 5-ATN, 20 g (0.235 mols) of anhydrous 5-AT is placed in an ice bath then neutralized with 22 mL (0.350 mols) of concentrated nitric acid. It is then stirred for about one hour [833]. Following that, about 70 mL of water is added directly to the slurry and the entire mixture is then heated quickly to boiling. The hot solution is vacuum filtered and allowed to cool at ambient conditions while stirring. The white crystals formed during cooling are vacuum filtered and washed with cold water, then forced through a No. 14 mesh screen to form granules. The wet material is dried in air at ambient conditions and forms well-flowing granules. Using TGA, the 5-ATN dried at ambient conditions was found to contain about 1.0 mass-% water. As tested on a Bureau of Explosives (BOE) impact apparatus, the air-dried material showed no pos-

itive fires at drop heights up to 25 in. (equivalent to about 231 kg cm). However, when 5-ATN granules were dried at 105 °C for 4 h to remove any remaining moisture, this material showed positive fires at about 4 in. (equivalent to about 37 kg cm). This demonstrates how 5-ATN becomes more sensitive to impact stimuli when completely dry. The dried 5-ATN was tested using a DSC at a heating rate of 10 °C/min. The 5-ATN melted at 429.9 K (156.8 °C) and then decomposed exothermically with an onset of exotherm at 450.3 K (177.2 °C) and a peak at 455.6 K (182.5 °C). The 5-ATN was also tested using a TGA at a heating rate of 10 °C/min and found to have an 89.3 mass-% gas conversion up to 723 K (450 °C), with a 67.5 mass-% gas conversion up to about 467 K (194 °C). The DSC and TGA data show that the 5-ATN auto-ignites at about 453 K (180 °C) with a large release of energy. Gas generant compositions were patented with a combination of 5-ATN and an oxidizer. The oxidizer may be selected from a group, including non-metal and metal nitrates, nitrites, chlorates, chlorites, perchlorates, or oxides.

5-Aminotetrazolium nitrate is obtained in good yield through direct neutralization of a 5-AT base with dilute nitric acid in an aqueous solution and can be crystallized and recrystallized from water and/or methanol [834]. The crystalline salt was characterized using Raman and multi-nuclear ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{15}\text{N}$ ) NMR spectroscopy. The molecular structure of 5-aminotetrazolium nitrate in the crystalline state was determined by XRD and found to be monoclinic, space group  $P2_1/c$ ,  $a = 1.05493(8)$  nm,  $b = 0.34556(4)$  nm,  $c = 1.4606(1)$  nm,  $\beta = 90.548(9)^\circ$ ,  $V = 0.53244(8)$  nm<sup>3</sup>,  $Z = 4$ , and  $\rho_{\text{X-ray}} = 1.847$  g/cm<sup>3</sup>. The thermal stability of 5-aminotetrazolium nitrate was determined using DSC; the compound decomposed at 440 K (167 °C). The heat of combustion of 5-aminotetrazolium nitrate was determined experimentally using oxygen bomb calorimetry and found to be  $6020 \pm 200$  kJ/kg. The standard enthalpy of formation ( $\Delta H_{298}^\text{f}$ ) of 5-aminotetrazolium nitrate was calculated using quantum mechanical considerations at the electron-correlated *ab initio* MP2 (second-order MP2 perturbation theory) level of theory and found to be +87 kJ/mol = +586 kJ/kg. The theoretical detonation velocity and the detonation pressure of 5-aminotetrazolium nitrate were calculated using the empirical equations by Kamlet and Jacobs and predicted to be 8.90 mm/s and 35.7 GPa.

A series of nitrogen-rich molecules including 5-aminotetrazolium nitrate and hydrazinebistetrazole were studied using laser-induced breakdown spectroscopy [835]. The atomic emission intensities and intensity ratios of the constituent elements were shown to correlate with the mol fractions and stoichiometries of the molecules. In addition, the amount of oxygen present in the molecule influenced the emission intensities of molecular fragments such as  $\text{C}_2$ .

5-Aminotetrazolium nitrate (5-ATN) can be synthesized from 5-aminotetrazole monohydrate ( $5\text{-AT} \cdot \text{H}_2\text{O}$ ) and concentrated nitric acid. The effect of nitric acid dosage, reaction time, and reaction temperature on the yield of 5-ATN was measured to optimize the yield [836]. The best synthesis conditions determined by orthogonal experiments were as follows: 5 g 5-AT, 15 mL nitric acid, reaction temperature 293 K

(20 °C), and reaction time 15 min. (with a yield of 92.6%). Compared with previous studies, the reaction temperature and time were decreased while the yield improved. SEM picture showed that the surface of 5-ATN was smooth, and humidity storage tests showed that the unwanted water absorption of the product was reduced.

5-Aminotetrazolium nitrate (5-aminotetrazole nitrate) and oxidizing potassium salts are used in gas generant formulations along with the parent compound 5-AT. One example for a gas generant formulation incorporates a combination of 5-aminotetrazole nitrate and an oxidizer [837]. The oxidizer may be selected from a group, which can include non-metal and metal nitrates, nitrites, chlorates, chlorites, perchlorates, and oxides. 5-Aminotetrazole nitrate is characterized as an oxygen-rich fuel and is therefore considered to be a self-deflagrating fuel. To tailor the oxygen balance in certain applications, however, the use of an oxidizer is preferred. These compositions are used for inflating airbags and actuating seatbelt pretensioners in passenger-restraint devices. 5-Aminotetrazolium nitrate can be used in the synthesis of glycidyl nitrate [838].

### 13.2 5-Aminotetrazolium Perchlorate

Protonation of 5-amino-1*H*-tetrazole with perchloric acid in water gave 5-amino-1*H*-tetrazolium perchlorate (**1**) in good yield and purity, or an adduct (**2**) of (**1**) with excess 5-AT depending on the experimental conditions used [839]. 5-Amino-1*H*-tetrazolium perchlorate can also be prepared by metathesis of 5-amino-1*H*-tetrazolium bromide with anhydrous silver perchlorate in an alcoholic solution. Both perchlorate salts were characterized by NMR, Raman and IR spectroscopy, DSC, MS, and elemental analysis. The crystal structures of compounds (**1**) and (**2**) were determined by XRD. Both salts crystallized in monoclinic cells in the space group  $P2_1/n$  (**1**)  $a = 5.3691(6) \text{ \AA}$ ,  $b = 7.8470(6) \text{ \AA}$ ,  $c = 15.2770(13) \text{ \AA}$ ,  $\beta = 91.381(8)^\circ$ ,  $V = 643.45(10) \text{ \AA}^3$ ,  $Z = 4$ ,  $\rho = 1.915 \text{ g/cm}^3$ , and (**2**)  $a = 5.2615(1) \text{ \AA}$ ,  $b = 8.5311(2) \text{ \AA}$ ,  $c = 21.4870(4) \text{ \AA}$ ,  $\beta = 96.127(1)^\circ$ ,  $V = 958.96(3) \text{ \AA}^3$ ,  $Z = 4$ , and  $\rho = 1.874 \text{ g/cm}^3$ . With an impact and friction sensitivity of  $I = 1.5 \text{ J}$  and  $F = 8 \text{ N}$ , respectively, and an ESD sensitivity of  $0.1 \text{ J}$ , perchlorate (**1**) is a powerful primary explosive, whereas the presence of a second tetrazole ring in (**2**) makes it a very stable compound ( $I = 22 \text{ J}$ ,  $F = 260 \text{ N}$ ,  $\text{ESD} = 0.4 \text{ J}$ ).

The enthalpy of formation of 5-aminotetrazolium perchlorate  $\text{C}_4\text{H}_4\text{N}_5\text{O}_4\text{Cl}$  ( $M = 185.53 \text{ g/mol}$ ) is  $+204 \text{ cal/g} = +37.8 \text{ kcal/mol} = +158.3 \text{ kJ/mol}$ . The enthalpies of formation of 12 salts formed by the reaction of the bases 4-amino-1,2,4-triazole (**A**), 1-amino-1,2,4-triazole (**B**), and 5-aminotetrazole (**C**) upon reaction with the acids  $\text{HNO}_3$ ,  $\text{HN}(\text{NO}_2)_2$ ,  $\text{HClO}_4$ , and  $\text{HC}(\text{NO}_2)_3$  were studied using DFT calculations [270]. For the production of energetic salts, 5-aminotetrazole and  $\text{HClO}_4$  were identified as the preferred base and acid, respectively.

### 13.3 5-Aminotetrazolium Dinitramide

5-Aminotetrazolium dinitramide (5-aminotetrazolium dinitramide) is one of the most promising candidates for energetic high-nitrogen compounds [840, 841]. The highly energetic isomers azidoformamidinium dinitramide and 5-aminotetrazolium dinitramide were synthesized by the reaction of potassium dinitramide and azidoformamidinium perchlorate or 5-aminotetrazolium perchlorate, respectively [751]. Both compounds have an oxygen balance of  $O = 0.0$ , which means they are perfectly balanced to burn to nothing else but  $\text{CO}_2$  and  $\text{H}_2\text{O}$  (besides  $\text{N}_2$ ). 1*H*-tetrazolium dinitramide and 2-methyl-5-aminotetrazolium dinitramide were synthesized using 1*H*-tetrazolium perchlorate and 2-methyl-5-aminotetrazolium perchlorate. A full characterization of the chemical properties (single-crystal XRD, IR and Raman spectroscopy, multi-nuclear NMR spectroscopy, DSC, and MS) and energetic characteristics were measured and the HOFs were calculated (CBS-4M) by MO computational methods. 1*H*-tetrazolium perchlorate is very hygroscopic and it was difficult to obtain XRD spectra of the dry salt.

### 13.4 Other 5-Aminotetrazolium Salts

5-Amino-1*H*-tetrazolium halogenide salts (Cl, Br, I) are useful starting materials to synthesize energetic materials by metathesis reactions. Hydrate halide salts of 5-amino-1*H*-tetrazole (5-ATHX, X = Cl, Br, I) were synthesized and characterized [842]. The compounds were characterized by using elemental analysis, mass spectrometry, IR and Raman spectroscopy, multi-nuclear NMR ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{15}\text{N}$ ) spectroscopy, and DSC.

The nitroguanidine salt of aminotetrazole, 5-aminotetrazolium nitroguanidinate,  $\text{C}_2\text{H}_6\text{N}_9\text{O}_2$ , has a molecular mass of  $M = 188.13$  g/mol and is registered as CAS RN [92260-29-2].

5-Aminotetrazolium nitroguanidinate

### 13.5 5-Aminotetrazolate Salts

5-Aminotetrazole (5-AT) behaves as a weak acid and can be used to obtain nitrogen-rich energetic salts and ionic liquids. Nine energetic nitrogen-rich salts based on 5-AT in anionic form were prepared, thus demonstrating that 5-AT is indeed amphoteric

[779]. Some of these salts had very low melting points and were stable nitrogen-rich ionic liquids that contain the 5-AT anion. This discovery was reported in [779] for the first time. In addition, three other energetic 5-aminotetrazolium salts were prepared for comparison. The properties of these aminotetrazolate and aminotetrazolium salts are summarized in Table 53. These 5-AT salts have been characterized by IR, NMR, elemental analysis, thermal stability, phase behavior, and density by gas pycnometer. 4-Amino-2-methyl-1,2,4-triazolium 5-aminotetrazolate has the highest nitrogen content (68%) of any known room-temperature ionic liquid.

The numbers in parentheses that follow refer to the compounds listed in Table 53. 1,4-Dimethyl-5-aminotetrazolium 5-aminotetrazolate (**4**) and 1,3-dimethyl-5-aminotetrazolium 5-aminotetrazolate (**5**) have been synthesized by metathesis reactions between silver 5-aminotetrazolate and a suitable tetrazolium iodide salt [843]. In addition to this, the free acid 1,4-dimethyl-5-iminotetrazole (**7**) was synthesized by deprotonation of 1,4-dimethyl-5-aminotetrazolium iodide using potassium hydroxide. Further to this, 1,4-dimethyl-5-iminotetrazole (**7**) was alternatively used to synthesize (**4**). All three compounds (**4**, **5**, and **7**) were characterized using analytical and spectroscopic methods and the crystal structures of (**4**) and (**7**) were determined by low-temperature XRD, with findings as follows:

1,4-Dimethyl-5-aminotetrazolium 5-aminotetrazolate (**4**) crystallized in monoclinic crystals, space group  $P2_1/n$ , with unit cell parameters of  $a = 6.7422(4) \text{ \AA}$ ,  $b = 9.8362(5) \text{ \AA}$ ,  $c = 13.0637(8) \text{ \AA}$ ,  $\beta = 97.985(5)^\circ$ ,  $V = 857.95(9) \text{ \AA}^3$ . 1,4-Dimethyl-5-iminotetrazole (**7**) crystallized in triclinic shape crystals, space group  $P\bar{1}$ , with unit cell parameters of  $a = 6.256(1) \text{ \AA}$ ,  $b = 6.773(1) \text{ \AA}$ ,  $c = 6.773(1) \text{ \AA}$ ,  $\alpha = 102.24(3)^\circ$ ,  $\beta = 97.96(3)^\circ$ ,  $\gamma = 100.39(3)^\circ$ ,  $V = 271(3) \text{ \AA}^3$ . The HOFs of (**4**) and (**5**) were experimentally determined using bomb calorimetry and their validity was checked against the results of quantum chemical calculations.

Whenever silver 5-aminotetrazolate is used in the synthesis of other compounds, one has to remember that it is very shock sensitive and should not be stored in the dry state [844]. Energetic 5-aminotetrazolium and 1, 5-diaminotetrazolium salts were readily synthesized by the reaction of 5-aminotetrazolium nitrate or 1,5-diaminotetrazolium nitrate with ammonium 5-nitroiminotetrazolate, ammonium 1-methyl-5-nitroiminotetrazolate, bis(ammonium) ethylene bis(5-nitroiminotetrazolate), or diammonium iminobis(5-tetrazolate) in water under mild conditions [845]. All products were recovered as highly crystalline materials in excellent yields and purities and were fully characterized by IR,  $^1\text{H}$ , and  $^{13}\text{C}$  NMR spectroscopy, DSC, and elemental analyses.

A T-jump/TOF mass spectrometer was used to probe the decomposition of several aminotetrazole-containing energetic materials (5-amino-1-methyl-1*H*-tetrazolium dinitramide, 1,5-diamino-4-methyl-1*H*-tetrazolium dinitramide, 1,5-diamino-1*H*-tetrazolium nitrate, 1,5-diamino-4-methyl-1*H*-tetrazolium azide, and 5-aminotetrazolium dinitramide) under very high heating rates of  $10^5$ – $10^6$  K/s [846, 847]. Subtle differ-

Table 53: Properties of energetic nitrogen-rich 5-aminotetrazolate salts.

Data source: [762].

ences between materials in functional group placement and anion composition allowed for further interpretation of the decomposition pathway of the tetrazole structure and various anions. Two decomposition pathways for the tetrazole ring were observed, which resulted in the primary formation of  $\text{HN}_3$  or  $\text{N}_2$ . The  $\text{N}_2$  formation pathway occurred when functional groups were placed symmetrically around the tetrazole ring, whereas asymmetric placement resulted in  $\text{HN}_3$  production. The azide salt had a lower decomposition temperature than the similar dinitramidate salt.

5-Aminotetrazole is amphoteric and can form 5-aminotetrazolium salts with acids as well as 5-aminotetrazolates with strong bases. Some of the 5-aminotetrazolates of heterocyclic amines and other nitrogen bases behave as ionic liquids and are difficult to crystallize. The melting points and enthalpies of formation of several of these that are of interest as high-nitrogen constituents for rocket propellants have been determined and are summarized in Tables 54 and 55 [779].

**Table 54:** Melting points and enthalpies of formation of 5-aminotetrazolate salts.

Data source: [762].

Hydrazinium 5-aminotetrazolate,  $\text{CH}_7\text{N}_7$ , has a density of  $1.48 \text{ g/cm}^3$  and an enthalpy of formation of  $383.60 \text{ kJ/mol}$  and melts at  $398 \text{ K}$ . It has a nitrogen content of  $83.73 \text{ mass-\%}$ .

Hydrazinium(1+) 5-aminotetrazolate

Hydrazinium 5-aminotetrazolate was synthesized via two facile routes. Both the reaction of 5-amino-1*H*-tetrazole with hydrazine hydrate in aqueous solution and the reaction of 5-amino-1*H*-tetrazole with diluted hydrazine solution in THF yielded hydrazinium 5-aminotetrazolate in excellent purities and good yields [848]. Hydrazinium 5-aminotetrazolate can be recrystallized from hot ethanol yielding colorless needle-shaped crystals which can be washed with diethyl ether. Hydrazinium 5-aminotetrazolate crystallizes in the chiral orthorhombic space group  $P2_12_12_1$  with four molecules in the unit cell. Hydrazinium 5-aminotetrazolate was characterized by XRD, IR, Raman, NMR spectroscopy, MS, elemental analysis, and DSC. The HOF was calculated to be  $+373 \text{ kJ/mol}$ . With this value and the X-ray density, several detonation parameters (heats of explosion, detonation pressure, detonation velocity, explosion temperature) were calculated. An astoundingly high value ( $9516 \text{ m/s}$ ) was obtained for the detonation velocity. Therefore, experimental tests to determine the velocity of detonation will have to be performed. However, despite a detonator with  $0.2 \text{ g}$  silver acetylide nitrate, a  $1 \text{ g}$  PETN, and a booster charge of  $2 \text{ g}$  PETN, the powder sample could not be detonated. The sensitivities towards impact, friction, and electrostatic discharge were determined with the BAM drop-hammer, friction tester, and an ESD test machine. It was found to be very insensitive (BAM drop-hammer:  $>100 \text{ J}$ ; friction tester:  $>360 \text{ N}$ , ESD:  $>3.0 \text{ J}$ ). The properties of hydrazinium 5-aminotetrazolate are summarized in Table 56. In addition to its use as an explosive, the use of hydrazinium 5-aminotetrazolate in solid propellant compositions was calculated and tested in combination with oxidizers, e.g., ADN.

The tautomerism of all possible forms of 5-aminotetrazole in the gas phase and solution was studied theoretically [849]. Computational chemistry calculations were performed and it was found that 5-aminotetrazole in the 2*H* form should be the most stable isomer in both the gas phase and in solution. In addition, the aggregation and proton exchange of various isomers of 5-aminotetrazole with hydrazine was investigated in the gas phase and in solution. This also gave the standard enthalpy of formations of the different structures of hydrazinium 5-aminotetrazolate in the gas phase, eventually narrowing it down to a single value for the standard enthalpy of formation of hydrazinium 5-aminotetrazolate. The calculated values were in excellent agreement with the experimentally reported HOF for the hydrazinium 5-aminotetrazolate.

**Table 56:** Properties of hydrazinium 5-aminotetrazolate.

| Formula        | CH <sub>7</sub> N <sub>7</sub> |

Data source: [848].

Bis(1,2,3-triaminoguanidinium) bis(5-aminotetrazolate) monohydrate,  $2[\text{CH}_3\text{N}_6^+] \cdot 2[\text{CH}_2\text{N}_5^-] \cdot \text{H}_2\text{O}$ ,  $M = 396.4$ , is a high-nitrogen compound [850]. It crystallized in monoclinic, space group  $C2/c$  crystals with  $a = 10.448(2)$  Å,  $b = 10.387(1)$  Å,  $c = 15.544(3)$  Å,  $\beta = 93.11(1)^\circ$ ,  $V = 1684.4(5)$  Å<sup>3</sup>,  $Z = 4$ , and  $\rho_{X\text{-ray}} = 1.56$  g/cm<sup>3</sup>.

Energetic mono and dianionic 5-dinitromethyltetrazolate salts, prepared by combining stoichiometric amounts (1:1 or 1:2 mol ratio) of 5-dinitromethyltetrazole and various azoles and amines, exhibit thermodynamic properties as well as detonation velocities and pressures that make them competitive with some common energetic materials [851]. Aminoguanidinium 5-dinitromethyltetrazolate exhibited different particle shapes when crystallized from solutions of varying concentrations. Di(aminoguanidinium) 5-dinitromethyltetrazolate, when treated with a solvent-diffusion process, produced nano-particles with a branched net structure.

Aminoguanidinium 5-dinitromethyltetrazolate

5-Aminotetrazolate (5-AT) salts based on eight different di- and tri-substituted imidazolium cations were synthesized and characterized by IR and NMR spectroscopy and elemental analysis [198] (see the imidazolium salt section) (see also [852]).

## 14 Other Tetrazole Compounds

### 14.1 5-Hydrazino-1*H*-tetrazole

5-Hydrazino-1*H*-tetrazole, 5-tetrazolylhydrazine,  $\text{CH}_4\text{N}_6$ ,  $M = 100.083 \text{ g/mol}$ , is a nitrogen-rich compound that contains 83.97 mass-% nitrogen and has an oxygen balance of -63.9%. It melts at 472 K (199 °C) and decomposes at 480 K. 5-Hydrazinotetrazole can be obtained via the decomposition of 5,5'-azotetrazole [253]. The IR spectrum of 5-tetrazolylhydrazine is shown in Figure 18.

**Figure 18:** IR Spectrum of 5-hydrazino-1*H*-tetrazole. (Reproduced and modified from [722], with permission from the Levering Estate.)

5-Hydrazinotetrazole and 5-aminotetrazole have spectra that are markedly similar. The strong band at 6.0  $\mu\text{m}$  is believed due to the amino grouping present. Absorption bands were present in the four regions characteristic of aromatic amines, which were medium bands at 2.8 to 3.3  $\mu\text{m}$  and 12.5 to 15  $\mu\text{m}$ , and strong bands at 6.08 to 6.23 and 7.5 to 8.0  $\mu\text{m}$ . Three bands were found in the spectrum of 5-hydrazinotetrazole which were not in the spectrum of 5-aminotetrazole; these were at 8.97, 10.35, and 12.93  $\mu\text{m}$ . These were found to correspond to bands in hydrazine itself.

The acid hydrolysis of azotetrazole (5,5'-azoditetrazole) anion with dilute acids gives 5-hydrazinotetrazole. However, other high nitrogen products have also been isolated, one of which is explosive [853]. 5-Hydrazinotetrazole was synthesized with 5,5'-azotetrazolate as the starting material by acidifying with hydrochloric acid and

recrystallizing [854, 855]. Its structure was characterized by FTIR, melting point, and elemental analyses. The yield of 5-hydrazinotetrazole was 55–60% and the melting point was 469–472 K (196–198.9 °C).

Eight high-density energetic salts that contained the 5-hydrazino-1*H*-tetrazolium cation and oxidizing or nitrogen-rich anions were synthesized and characterized by IR,  $^1\text{H}$  and  $^{13}\text{C}$  NMR, elemental analysis, DSC, and impact sensitivity [856]. Four compounds were characterized by single-crystal XRD. The results showed that the extensive hydrogen-bonding interactions between the cations and anions form a complex 3-D network, which contributes greatly to the high density of the 5-hydrazinotetrazolium salts. It was also found that the incorporation of hydrazino groups into a heterocyclic ring increased the HOF and the overall nitrogen content of the entire molecule. In addition, calculated detonation properties of the energetic salts identified them as competitively energetic compounds. In some cases, they were viewed as even superior to those of HMX. The properties of hydrazinotetrazolium salts are summarized in Table 57.

## 14.2 5-Cyanotetrazole

5-Cyanotetrazole, 5*H*-tetrazole-5-carbonitrile,  $\text{C}_2\text{H}_1\text{N}_5$ , CAS RN [1004771-58-7],  $M = 95.07\text{ g/mol}$ , is a stable high-nitrogen compound with 73.7% N. It melts at 372 K (99 °C). It is slightly acidic and forms salts with many nitrogen-containing bases. The enthalpy of formation of 5-cyanotetrazole is  $+1010\text{ cal/g} = 96.02\text{ kcal/mol} = 402\text{ kJ/mol}$ .

The reaction of cyanogen ( $\text{NC-CN}$ ) with  $\text{MN}_3$  ( $M = \text{Na, K}$ ) in liquid  $\text{SO}_2$  leads to the formation of the 5-cyanotetrazolate anion as the monohemihydrate sodium or potassium salts, respectively [857]. Both can be used as starting materials for the synthesis of salts containing the 5-cyanotetrazolate anion and nitrogen-rich cations, namely ammonium, hydrazinium, semicarbazidium, guanidinium, aminoguanidinium, diaminoguanidinium, and triaminoguanidinium. Several salts were characterized by low-temperature single-crystal XRD, as detailed in Table 58. DSC and sensitivity tests were used to assess the thermal stability and sensitivity against impact and friction. Constant volume energies of combustion, detonation velocity, and the pressure of the salts were calculated.

Looking at the energetic salts of cyanotetrazolate-1- and -2-oxides offers a unique opportunity to compare the effects of tetrazole 1- versus 2-oxidation. 5-Cyanotetrazole-2-oxide can be synthesized by oxidation of the 5-cyanotetrazolate anion with Oxone, while the corresponding 1-oxide can be synthesized by the rearrangement of azidoaminofurazan [858]. Both chemical (multi-nuclear NMR, IR and Raman spectroscopies, mass spectrometry, etc.) as well as explosive (impact, friction, and ESD sensitivities) properties were measured for these energetic salts, and predicted explosive performances were calculated using the EXPLO5 computer code.

**Table 58:** Crystal structures of 5-cyanotetrazolate salts.

Data source: [857].

The reaction of tetracyanoethylene and sodium azide in DMF leads to the production of the sodium salt of 5-tricyanovinyltetrazole, 2-(1*H*-tetrazol-5-yl)ethene-1,1,2-tricarbonitrile, C<sub>6</sub>HN<sub>7</sub>, which is a high-energy compound [859].

5-Tricyanovinyltetrazole

The dianion of 5-cyanoiminotetrazoline (C<sub>2</sub>N<sub>6</sub><sup>2-</sup>) represents a nitrogen-rich binary CN anion, forming salts with surprisingly high thermal stability [860].

Dianion of 5-cyanoiminotetrazoline

A variety of salts of 5-cyanoiminotetrazoline was prepared and the cesium salt was found to have a surprisingly high melting point of 607 K (334 °C). Metal complexes with 5-cyanotetrazole, 5-nitrotetrazolium, and 5-aminotetrazole as ligands were prepared and tested [861].

### 14.3 5-Azido-1*H*-tetrazole

5-Azidotetrazole, tetrazolylazide  $\text{CHN}_7$ , is closely related to tetrazolium azide but the properties are quite different [862]. 5-Azidotetrazole can easily isomerize to a bicyclic tetrazole.

5-Azido-1*H*-tetrazole (tetrazyl azide, tetrazolyl azide,  $\text{CHN}_7$ ,  $M = 111.07$ ) contains 88.29 mass-% nitrogen and is one of the most nitrogen-rich organic compounds. It is very sensitive and will explode at the slightest touch. It melts at 347–348 K (74–75 °C) and begins to decompose at 438 K = 165 °C. Tetrazolyl azide can be prepared in three ways: by reacting 5-hydrazinotetrazole with sodium nitrite and hydrochloric acid at 273 K (0 °C); by reaction of cyanogen bromide and sodium azide in water; and from the Cu salt of 1-guanyl-4-nitrosaminoguanyltetrazene following treatment with acid. A quite uncommon reaction is the alkaline degradation of the primary explosive tetracene using  $\text{Ba}(\text{OH})_2$ . 5-Azidotetrazolate salts, especially that of silver, are hypersensitive to mechanical stimuli. The azido group has a relatively strong absorption band in the region of 4.67 and 7.8–8  $\mu\text{m}$  (Figures 19 and 20).

Due to the highly explosive nature of 5-azido-1*H*-tetrazole, its characterization has not been fully achieved and described in the literature yet. The previously published crystal structure was of low quality and, therefore, the position of the hydrogen atom was not certain. To resolve these problems, 5-azido-1*H*-tetrazole was prepared in an improved synthesis, then reinvestigated and recharacterized [863]. The reaction of cyanogen bromide with two equivalents of sodium azide at low temperatures yielded sodium 5-azidotetrazolate, which was protonated using dilute hydrochloric acid.

5-Azido-1*H*-tetrazole synthesis

**Figure 19:** IR Spectrum of 5-azidotetrazole in hydrocarbon oil. (Reproduced and modified from [722], with permission from the Levering Estate.)

**Figure 20:** IR (top) and Raman (bottom) spectra of 5-azidotetrazole. (Republished and modified from [863], with the permission of ©2008 John Wiley & Sons; permission conveyed through RightsLink.)

The product 5-azido-1*H*-tetrazole was isolated and characterized using multi-nuclear ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{15}\text{N}$ ) NMR, IR, Raman, MS, and XRD. The HOF of 5-azido-1*H*-tetrazole was calculated using quantum mechanical methods, giving an enthalpy of formation of solid 5-azido-1*H*-tetrazole as  $\Delta H_f^{o298}(\text{S}) = +611 \text{ kJ/mol}$ . Further to this, several detonation parameters were estimated using the EXPLO5 software, giving a calculated detonation pressure of 327 kbar and a detonation velocity of 8986 m/s, which is higher than those of TNT or RDX. The X-ray structure showed monoclinic crystals, space group  $P2_1/c$ ,  $a = 13.265(2) \text{ \AA}$ ,  $b = 4.9693(6) \text{ \AA}$ ,  $c = 16.304(3) \text{ \AA}$ ,  $\beta = 127.04(1)^\circ$ ,  $V = 857.9(3) \text{ \AA}^3$ ,

$Z = 8$ , and  $\rho = 1.720 \text{ g/cm}^3$ . The position of the hydrogen atom at the nitrogen atom N1 was confirmed by a strong hydrogen bond. The HOF of 5-azido-1*H*-tetrazole was calculated and several detonation parameters were estimated. The thermal behavior was investigated using DSC and the sensitivity was tested using the BAM drop-hammer, ESD, and friction tester.

Several salts containing the 5-azido-1*H*-tetrazolate  $\text{CN}_7^-$  anion were prepared by the deprotonation of 5-azido-1*H*-tetrazole [864]. The highly explosive compounds hydrazinium, ammonium, aminoguanidinium, guanidinium, lithium, sodium, potassium, cesium, and calcium azidotetrazolate were prepared and characterized by low-temperature single-crystal XRD, IR, Raman, multi-nuclear NMR spectroscopy, mass spectrometry, and DSC. Not all salts could be characterized since some of the metal salts exploded spontaneously. Hydrazinium 5-azido-1*H*-tetrazolate contains the highest nitrogen content (87.48%) of all known tetrazole salts. The impact, friction, and ESD sensitivity of several salts were measured and the theoretical detonation pressure, velocity, and specific impulse were calculated. Ammonium 5-azidotetrazolate has been patented as a foaming agent for foamed plastics [865].

DFT computational methods were used to predict the properties of azidoazole compounds, and the structures, energetic properties, and decomposition mechanisms of compounds, such as 2-azido-1,3-imidazole (I), 3-azido-1*H*-1,2,4-triazole (II), 5-azido-1*H*-tetrazole (III), and azido-pentazole (IV) [866]. The energy performance was examined by calculating the specific impulse. The order of increasing specific impulses was  $\text{I} < \text{II} < \text{III} < \text{IV}$ . The predicted specific impulse of III and IV was higher than that of HMX. Decomposition mechanisms were investigated by considering various possible weak trigger bonds as well as the azide  $\leftrightarrow$  azole isomerization. It was predicted that the azide  $\leftrightarrow$  azole isomerization participates in the pyrolysis of I and II but not III and IV. The pyrolysis of III starts from the breakage of N1–N2 and that of IV from the synergistic rupture of N2–N3 and N4–N5. The low activation energies in the pyrolysis suggest III and IV will be quite unstable.

#### 14.4 5-Methyl-1*H*-Tetrazole

5-Methyl-1*H*-tetrazole,  $\text{C}_2\text{H}_4\text{N}_4$ , CAS RN [4076-36-2], melts at 415–419 K (142–146 °C) and is thermally stable, however, there are no known uses as a rocket propellant or gas generant. Methyltetrazoles are of relatively little interest as rocket propellants or gas generants. Nevertheless, we do have data on their melting points, enthalpies of formation, and heat of fusion, as summarized in Table 59 [867], which also provides a comparison to the unsubstituted tetrazole and the more popular 5-aminotetrazole. Some of these compounds are liquids at room temperature. Vapor pressures, heat of

**Table 59:** Properties of tetrazole, 5-aminotetrazole, and several methyltetrazoles.

Data source: [867].

vaporization or sublimation, and entropies of fusion and evaporation were also listed in the original publication but are not included in Table 59.

## 14.5 Di-substituted Neutral Tetrazole Derivatives

1,5-Dimethyl-1*H*-tetrazole, C<sub>3</sub>H<sub>6</sub>N<sub>4</sub>, CAS RN [5144-11-6], can be used as the starting ingredient in other tri-substituted tetrazole derivatives. Substituted tetrazoles can be made from nitriles instead of cyanamide and hydrazoic acid [868].

### 14.5.1 1,5-Diamino-1*H*-tetrazole

1,5-Diaminotetrazole, tetrazole-1,5-diamine, C<sub>1</sub>H<sub>4</sub>N<sub>6</sub>, DAT, CAS RN [2165-21-1], *M* = 100.09 g/mol, is a useful intermediate in the synthesis of other more energetic tetrazole derivatives. 1,5-Diaminotetrazole melts at 460–461 K (187–188 °C) (dec.). 2,5-Diaminotetrazole melts at 398–400 K (125–127 °C) (dec.).

1,5-Diamino-tetrazole (DAT)

1,5-Diaminotetrazole can be synthesized from thiosemicarbazide and sodium azide in the presence of lead(II) oxide and ammonium chloride in DMF as the solvent [869]. Unfortunately, this method results in the formation of lots of lead azide, which is difficult to dispose of due to its shock sensitivity. A summary of synthesis methods for DAT is provided in [870].

A milestone in the synthesis of DAT was achieved when chemists reacted the sodium salt of 5-aminotetrazole with hydroxylamine-*O*-sulfonic acid and obtained a mixture of 1,5-diaminotetrazole (1,5-DAT) and 2,5-diaminotetrazole (2,5-DAT), where the first constituted ~8.5% of the reaction yield [871].

A method developed at the Klapoetke group in Munich avoids the formation of lead azide and instead uses the diazotation of diaminoguanodinium chloride. This reaction mixture is brought to pH 8 to deprotonate the intermediate formed, which cyclizes, thus yielding 1,5-DAT in 58% yield. That method is similar to the scheme developed by Galvez-Ruiz. The synthesis conditions must be perfectly controlled because the reaction of nitrous acid with aminoguanidinium is strongly dependent on the pH value as well as on the amounts of reactants. Otherwise, it might lead to the azide derivative, which is a very explosive byproduct.

Another synthesis method for 1,5-diamino-1*H*-tetrazole was introduced that avoided azide as a hazardous byproduct. 1,5-diamino-tetrazole can be prepared by the diazotization of a solution of diaminoguanidinium chloride in water with sodium nitrite, followed by extraction with hot EtOH. Once the extracting solvent leaves via evaporation, pure 1,5-diamino-1*H*-tetrazole remains. This can be recrystallized from water and has a melting point of 458–460 K (185–187 °C) [872].

1,5-Diaminotetrazole Synthesis

An improved synthesis method for 1,5-diamino-1*H*-tetrazole also uses the diazotization of diaminoguanidinium chloride [819]. Another synthesis method oxidizes

thiosemicarbazide with lead oxide and reacts the intermediate *N*-aminocarbodiimide with hydrazoic acid.

1,5-Diamino-1*H*-tetrazole derivatives can be obtained by reaction of mono-substituted hydrazines such as 2,5-dihydrazinotetrazine with cyanogen azide [873]. Azido-hydrazones were postulated as intermediates in this reaction (see scheme).

1,5-Diamino-1*H*-tetrazole is best prepared starting with diaminoguanidinium(1+) chloride as a precursor raw material [874]. 1,5-Diamino-tetrazole isomerization reaction kinetics were studied based on DFT methods. The geometry structure, vibration frequencies, natural bonding orbital, and zero-point energy (ZPE) of stationary points involved in the reaction were calculated [754]. The isomerization reaction displays azide-cyclization mechanisms. In the gaseous case, the reaction is exothermic and spontaneous, with a low reaction activation energy.

A DFT method was applied to compute bond energies and electronic structures of 1,5-diamino tetrazole in both gaseous and crystalline states [875]. The crystal structure compared well with experimental data. The overlap populations of N(1)–N(2) bonds were much less than those of other bonds. Therefore the N(1)–N(2) bond was predicted to first rupture by external stimuli.

#### 14.5.2 Nitroalkyl Di-Substituted Tetrazole Derivatives

Combining trinitroethyl functionality with mono-, di- or triaminotriazoles via a Mannich reaction with trinitromethane and formaldehyde results in very energetic materials such as 1-trinitroethylamino-5-amino-tetrazole (TTD) or 1,5-bis-(trinitroethylamino)tetrazole (BTDD) [876]. TTD has an enthalpy of formation of +356 kJ/mol, a density of 1.831 g/mL, a detonation velocity of 9194 m/s, and an impact sensitivity of 30 J. However, it has poor thermal stability with an onset of exotherm at 399 K (126 °C).

A series of dense energetic *N*-trinitroethyl-substituted mono-, bis-, and tri-aminotetrazoles were obtained by reacting primary amines with *in-situ* generated cyanogen azide. This was followed by the trinitroethyl functionalization, which involved a condensation of a hydroxymethyl intermediate prepared by a reaction of formaldehyde with trinitromethane [877]. These compounds were characterized by NMR, IR, elemental analysis, DSC, and XRD. The HOFs for all compounds were calculated and then combined with experimental densities to determine the detonation pressures and velocities of the energetic materials. For tetrazole- and tetrazine-based high-density energy compounds with oxygen balance equal to zero see Reference [726].

Convenient access to 5-(trinitromethyl)-2*H*-tetrazole (HTNTz) has been developed by the exhaustive nitration of 1*H*-tetrazole-5-acetic acid [878]. HTNTz was converted into ammonium, guanidinium, rubidium, cesium, copper, and silver 5-(trinitromethyl)-2*H*-tetrazolates. The reaction of HTNTz with hydrazine or hydroxylamine resulted in the loss of one nitro group from the alkyl rest and the formation of hydrazinium 5-(**d**initromethyl)tetrazolate and hydroxylammonium 5-(**d**initromethyl)-1*H*-tetrazolate, respectively. Acid treatment of both 5-(**d**initromethyl)tetrazolates resulted in the isolation of 5-(dinitromethylene)-4,5-dihydro-1*H*-tetrazole, which was then converted into potassium 5-(dinitromethyl)-1*H*-tetrazolate by reaction with  $K_2CO_3$ . The 5-(trinitromethyl) and 5-(dinitromethyl)tetrazoles are highly energetic materials that explode upon impact or heating.

A series of di-, tri-, and tetrakis-tetrazoloalkanes were synthesized from the corresponding nitriles and sodium azide [879]. These were then alkylated to give hydroxy-terminated chains for possible use as high-energy oligomers in energetic binders for solid propellants.

Diols with tetrazole rings and alkyl groups between the two oxygen atoms can be used as building blocks for high-nitrogen polymers. These are suitable for solid propellants, gas generants [880–888], and low-temperature clean-burning pyrotechnic gas generators [889].

1-(2-Nitratoethyl)-5-nitriminotetrazole was formed by the reaction of 1-(2-hydroxyethyl)-5-aminotetrazole and 100%  $\text{HNO}_3$  [890].

1-(2-Nitratoethyl)-5-nitriminotetrazole

This compound has acidic properties and forms salts with bases. Nitrogen-rich salts such as the ammonium, hydroxylammonium, guanidinium, aminoguanidinium, diaminoguanidinium, and triaminoguanidinium 1-(2-nitratoethyl)-5-nitriminotetrazolate were prepared and characterized by single-crystal XRD, IR and Raman spectroscopy, multi-nuclear NMR, elemental analysis, and DSC. The enthalpies of formation were calculated and several detonation parameters such as the detonation pressure, velocity, energy, and temperature were computed. The sensitivities towards impact, friction, and electrical discharge were tested using the BAM drop-hammer impact sensitivity test apparatus, a friction sensitivity tester, as well as a small-scale electrical discharge device.

Hydroxylammonium 2-dinitromethyl-5-nitrotetrazolate (HADNMNT) crystal structure was determined by  $^{15}\text{N}$  NMR and gauge independent atomic orbital (GIAO) calculations [891]. The thermal decomposition temperature, the explosion probabilities of impact sensitivity, and the friction sensitivity were 141.9 °C, 96%, and 100%, respectively. The detonation parameters of HADNMNT were predicted to be equal to those of HMX.

### 14.5.3 Other Neutral Di-Substituted Tetrazole Derivatives

1-Methyl-5-nitrotetrazole and 2-methyl-5-nitrotetrazole have been evaluated as initiating explosives [892]. Although isomers, they exhibited markedly different thermal and explosive properties. 2-Methyl-5-nitrotetrazole is an energetic material with properties both of primary and secondary explosives. It is sensitive to mechanical and electrostatic shock comparable with primary explosives but does not ignite to explosion when unconfined.

The reaction of 1-chloro-2-nitro-2-azapropane with silver nitrotetrazolate yielded 1-nitrotetrazolato-2-nitro-2-azapropane (NTNAP), also known as *N*-methyl-*N*-[(5-nitrotetrazol-2-yl)methyl]nitramide, as a white solid substance [819, 893]. The highly energetic compound was characterized using vibrational (IR and Raman) and multi-nuclear ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ) NMR spectroscopy, elemental analysis,

and low-temperature single-crystal XRD. 1-Nitrotetrazolato-2-nitro-2-azapropane is a covalently bound room-temperature stable solid that contains a nitramine group and a nitrotetrazolate ring unit in the molecule. It was hydrolytically stable at ambient conditions.

1-Nitrotetrazolato-2-nitro-2-azapropane

This compound has an oxygen balance of  $-35.5\%$ , impact sensitivity of 6 J, and friction sensitivity of 60 N. The covalent compound is thermally reasonably stable, melts without decomposition at 373 K ( $100^\circ\text{C}$ ), and shows decomposition with an onset of exotherm at about 453 K ( $180^\circ\text{C}$ ).

The synthesis of 1-methyl-5-(1-methyl-2-(2,2,2-trinitroethyl)hydrazinyl)-1*H*-tetrazole (MMTHT) and 2-(5-(1-methyl-2-(2,2,2-trinitroethyl)hydrazinyl)-1*H*-tetrazol-1-yl)ethanol (MTHTE) utilizes a condensation of the starting amino derivative with 2,2,2-trinitroethanol [819].

R = CH<sub>3</sub>, C<sub>2</sub>H<sub>5</sub>

1-Methyl-5-(1-methyl-2-(2,2,2-trinitroethyl)hydrazinyl)-1*H*-tetrazole, MMTHT, C<sub>5</sub>H<sub>9</sub>N<sub>9</sub>O<sub>6</sub>, has a molecular mass of 291.21 g/mol, an oxygen balance of  $-46.7\%$ , and a density of 1.63 g/cm<sup>3</sup>. The onset of decomposition by DSC (2 K/min) was relatively low at 355.6 K ( $82.5^\circ\text{C}$ ), impact sensitivity was  $>30$  J, friction sensitivity was 108 N (visible flame), the predicted detonation pressure was 277 kbar, and the detonation velocity was 8307 m/s.

The trinitromethyl and fluorodinitromethyl functionalities have proven to be useful functional groups in the synthesis of high-performing explosives as well as oxidizers for rocket propellants, such as 5-(polynitromethyl)-tetrazole and 2-(2-nitro-2-azapropyl)-5-(trinitromethyl)-2*H*-tetrazole [712, 894].

#### 14.5.4 Di-Substituted Tetrazoles: Nitro-Amino-Tetrazole and Nitro-Imino-Tetrazole

Nitriminotetrazoles and the corresponding metal nitramino-tetrazolates salts have been known for a long time; they are, after all, relatively cheap and easy to manufacture via various routes. There are two main methods employed to do this, the first of which uses the protonation of 5-aminotetrazole using warm concentrated  $\text{HNO}_3$  to form 5-aminotetrazole nitrate, followed by dehydration with concentrated  $\text{H}_2\text{SO}_4$  to form 5-nitriminotetrazole. Another synthetic route is based on the cyclization of nitroguanylazide (also known as nitroazidoformamidine). A third less frequently used method is the *N*-nitration of aminotetrazoles using tetranitromethane.

2-Amino-5-nitrotetrazole can be prepared by the amination of the parent anion with *O*-tosylhydroxylamine [318]. The 5-*H*-tetrazolate anion has also been aminated using the addition of hydroxylamine *O*-sulfonic acid to either 1-aminotetrazole or 2-aminotetrazole. The prepared materials have been characterized by XRD, NMR, IR, and Raman spectroscopy, and by mechanical impact and electrostatic discharge sensitivity testing. Their predicted explosive performances were calculated using the EXPLO5 computer code. The prepared *N*-amino energetic materials, which can also be used as new ligands for high-energy capacity transition metal complexes, exhibited high explosive performances (in the range of RDX and HMX) and a range of sensitivities from low to extremely high.

Oxy-5-aminotetrazoles can be obtained from the reaction of cyanogen azide and alkyl oxyamine in 100% nitric acid, giving a series of highly energetic oxy-5-nitroiminotetrazolates in good yield [895]. These compounds exhibited good physical and detonation properties, such as moderate thermal stabilities, high densities, high enthalpies of formation, high detonation pressures, and fast detonation velocities. For example, methylenebis(1-oxy-5-nitroiminotetrazole) had an enthalpy of formation of +3.47 kJ/mol, a density of 1.90 g/cm<sup>3</sup>, a detonation pressure of 46.7 GPa, and a detonation velocity of 9867 m/s.

Methylenebis(1-oxy-5-nitroiminotetrazole)

Highly energetic 1,1'-ethylenebis(oxy)bis(5-nitroimino-tetrazolate) salts can be obtained by reacting equimolar quantities of the acidic 1,1'-ethylenebis(oxy)bis-(5-nitroimino-tetrazole) and energetic bases in aqueous solution [230, 896]. Metathesis of silver 1,1'-ethylenebis(oxy)bis(5-nitroimino-tetrazolate) with diamino-guanidinium chloride or triaminoguanidinium chloride gave the corresponding oxy-nitroimino-tetrazolate salts. These salts were characterized by IR, NMR, ele-

mental analysis, DSC, and (in some cases) by single-crystal XRD. The HOFs for all compounds were calculated with Gaussian 03 and then combined with measured densities to calculate predicted detonation pressures and velocities. The impact sensitivities of all salts were found to be less than those of the parent compounds. The physical and detonation properties of these oxy-nitroimino-tetrazolate salts were comparable to the analogous diaminoguanidinium and triaminoguanidinium 1,1'-ethylenebis(5-nitroimino-tetrazolate) salts.

## 14.6 Di-Substituted Tetrazolium and Tetrazolate Salts

### 14.6.1 1,5-Diamino-1*H*-tetrazolium Salts

1,5-Diamino-1*H*-tetrazole (**2**, DAT) can easily be protonated by reaction with strong mineral acids like nitric acid or perchloric acid, yielding 1,5-diaminotetrazolium nitrate (**2a**) and perchlorate (**2b**). The numbers in parentheses refer to the compounds listed in Table 60. The reaction of 1,5-diamino-1*H*-tetrazole with iodomethane followed by the metathesis of the iodide with silver nitrate, silver dinitramide, or silver azide led to a new family of 1,5-diamino-4-methyl-1*H*-tetrazolium salts. The added methyl group goes into the 4-position. In all cases, stable salts were obtained and fully characterized by IR, Raman, MS, multi-nuclear NMR spectroscopy,

Table 60: Properties of 1,5-diaminotetrazolium salts.

| Comp. No. | Name                                                     | Formula                                                     | Melting point      |                    | Density (calc.) | Const. vol. heat of combustion |       | Enthalpy of formation |          | Det. pressure | Det. velocity |

Data source: [872].

elemental analysis, XRD, and safety testing (impact and friction sensitivity). Most of the salts exhibited good thermal stability. Both the perchlorate and the dinitramidate have melting points well below 373 K (100 °C), yet high decomposition onsets with maximum exotherm peaks at 441–465 K (168–192 °C) (except for the azide). Preliminary sensitivity testing of the crystalline compounds indicated rather low impact sensitivities for all compounds, the worst being that of the perchlorate and the dinitramide with a value of 7 J. The friction sensitivities of the 1,5-diamino-1*H*-tetrazole perchlorate and the 1,5-diamino-4-methyl-1*H*-tetrazolium dinitramidate were 60 and 24 N, respectively. The enthalpies of combustion ( $\Delta H_c^\circ$ ) of the salts were determined experimentally using oxygen bomb calorimetry. The HOFs calculated from these heats of combustion are summarized in Table 60 along with predicted detonation velocities and detonation pressures. The highly friction-sensitive 1,5-diamino-4-methyl-tetrazolium dinitramidate was also synthesized by a metathetical reaction of the corresponding iodide and silver dinitramidate [897].

1,5-Diamino-1*H*-tetrazole can easily form salts by reacting with strong acids. It also forms energetic complexes resulting from co-ordinating with six DAT molecules as ligands with metal perchlorates. All of these DAT complex compounds are sensitive to mechanical stimuli. They also possess good explosive properties.

A study of the combustion behavior of 1,5-diaminotetrazole (DAT), its salt with perchloric acid, and its coordination compounds with Ni(II), Co(II), Cu(II), Cd, and Zn perchlorates in the pressure range from 0.1 to 36 MPa showed that, despite the high energy content, 1,5-diaminotetrazole starts to burn only at extremely high pressures (above 24 MPa) [898, 899]. Diaminotetrazole perchlorate had the maximum burning rate among all known organic perchlorates. The burning rates of the coordination compounds were also very high, with the burning rate of  $[\text{Cu}(\text{DAT})_6](\text{ClO}_4)_2$  reaching the record value (for laminar combustion) of 1670 mm/s at a pressure of 34 MPa.

Energetic coordination compounds using 1,5-diaminotetrazole as ligand, Co or Cu as the central cation, and picric acid as the outer ion were synthesized and characterized by elemental analysis, FTIR spectroscopy, DSC, and TGA-DTG [900]. The two complexes accelerated the combustion of a GAP/HNIW propellant and the thermal decomposition of AP, HMX, and HNIW.

#### 14.6.2 1,5-Diaminotetrazolium Nitrate

Diaminotetrazole can form (1+), (2+), or (3+) tetrazolium nitrates or perchlorates, but the most common salts are the tetrazolium(1+) salts. In addition to the 1,5-diaminotetrazolium nitrate, the 1,5-diaminotetrazolium dinitramidate and perchlorate have also been investigated as HEDMs.

The presence of two amino groups on the tetrazole ring results in high-melting nitrate and perchlorate salts. If one wants to make ionic liquids, one should switch to amino/methyl tetrazolium compounds to achieve lower melting materials.

The heat of combustion of 1,5-diaminotetrazolium nitrate was determined experimentally using an oxygen bomb ( $\Delta H_{\text{comb.}} = 7900 \pm 300 \text{ kJ/kg}$ ) [901, 902]. The standard HOF of 1,5-diaminotetrazolium nitrate was obtained via *ab initio* quantum chemical computations ( $\Delta H_f^\circ = +254 \text{ kJ/mol} = +1558 \text{ kJ/kg}$ ). The detonation velocity ( $D$ ) and detonation pressures ( $P$ ) of 1,5-diaminotetrazolium nitrate were calculated using empirical equations by Kamlet and Jacobs, resulting in  $D = 8.77 \text{ mm}/\mu\text{s}$  and  $P = 33.3 \text{ GPa}$ .

*In-situ* synchrotron XRD, optical Raman, and IR spectroscopy were used to examine the structural properties, equation of state, and vibrational dynamics of 1,5-diaminotetrazolium nitrate under high pressure at room temperature [903]. The X-ray measurements showed that the pressure-volume relations remained smooth to 12 GPa. XRD measurements at pressures above 12 GPa were not possible in this study because of sample decomposition resulting from several factors. XRD revealed no indication of a phase transition to at least 12 GPa, but slight variations in the  $c/b$  unit cell ratio suggested modifications within the hydrogen bonding sub-lattice. Vibrational spectra indicated that the ambient phase of 1,5-diaminotetrazolium nitrate remained the dominant phase up to 33 GPa.

In a similar study, the isothermal structural properties, equation of state, and vibrational dynamics of 2-methyl-5-nitramino-2*H*-tetrazole were studied under high pressure using synchrotron XRD and optical Raman, and IR micro-spectroscopy [904]. Up to 15 GPa, analysis of the XRD patterns revealed no indication of a phase transition, and the pressure-volume isotherm remained smooth.

Three 1,5-diaminotetrazole nitro-substituted azolate salts were synthesized and characterized by IR, NMR, elemental analysis, thermal stability, phase behavior, density, and impact sensitivities [905]. The 1,5-diamino-4*H*-tetrazolium 5-nitrotetrazolate salts crystallized in the orthorhombic system *Pbca*. The predicted detonation pressure was from 28.05 to 29.88 GPa and the detonation velocities were from 8343 to 8655 m/s, thus making them competitive energetic materials. Most of the compounds had a slightly negative oxygen balance approaching zero (−23.8 to −33.5%).

1,5-Diaminotetrazolium nitrate ( $\text{CH}_5\text{N}_7\text{O}_3$ , HDATN) was synthesized from 1,5-diaminotetrazole as the raw material with a yield of 95.3% [906]. HDATN contains seven nitrogen atoms. Its nitrogen content is 60.1%, which is more than that of 5-aminotetrazolium nitrate (5-ATN). The structure was characterized by elemental analysis, IR spectrum, NMR, and mass spectrum. A possible fragmentation mechanism on heating was discussed. The thermal stability of the nitrate salt was investigated by TGA-DSC and DTA. In the DTA at  $5^\circ/\text{min}$ , there was an endotherm (melting) at 393.46 K (120.46 °C) but the mass did not change. HDATN started to break down after melting, with the first mass loss plateau seen from 400 to 430 K (127 to 157 °C), with an exotherm peak at 422 K (149 °C), and the second from 472 to 503 K (199 to 230 °C). The melting point shifted at higher heating rates to 419.9 K (144.75 °C). The kinetic parameters, including activation energy and pre-exponential factors, were calculated by using the Kissinger equation. The activation energy of the first decomposition step was

106.07 kJ/mol and that of the second step was 110.42 kJ/mol. The enthalpy of formation of the nitrate salt was measured as  $-271.78 \text{ kJ/mol} = -1667.36 \text{ cal/g}$ . The density was predicted from molecular calculations as  $1.713 \text{ g/cm}^3$ . The predicted detonation velocity was 8738 m/s with a pressure of 32.86 GPa.

### 14.6.3 1,5-Diaminotetrazole-Derived Energetic Salts

1,5-Diaminotetrazole is not a particularly strong base and will only form salts with relatively strong mineral acids ( $\text{pK}_a = 0$ ) under normal conditions. The direct reaction of 1,5-diaminotetrazole with concentrated perchloric acid formed the 1,5-diaminotetrazolium perchlorate [907]. The monoclinic, space group  $P2_1/n$  (No. 14), crystals with an X-ray density of  $1.909 \text{ g/cm}^3$  were sensitive to impact or friction. The crystals were soluble in a wide array of polar solvents such as methanol, ethanol, acetonitrile, DMSO, DMF, or water. In DSC studies, the material melted cleanly at 398–403 K (125–130 °C), followed by accelerating decomposition as the temperature was increased beyond the melting point. Experimental evidence strongly supported the protonation of a nitrogen atom of the tetrazole ring, including the structure observed in a single-crystal XRD. Quantum chemical calculations were performed to determine the relative energies of all possible *N*-protonated structures of the 1,5-diaminotetrazole ring. The predicted geometry of the most stable isomer compared favorably with the experimentally observed structure.

### 14.6.4 Other Di-Substituted Tetrazolium and Tetrazolate Salts

5-Amino-1-methyltetrazole and 5-amino-2-methyltetrazole can be obtained by methylation of the sodium salt of 5-aminotetrazole with dimethyl sulfate or methyl iodide. Di-substituted amino- and/or methyltetrazolium perchlorate salts with nitrate or perchlorate anions had higher melting points and decomposed at higher temperatures than the nitrate derivatives. The densities of these salts range between 1.5 and  $1.7 \text{ g/cm}^3$ . All six tetrazolium salts had positive  $\Delta H_f$ 's ranging between 130 to 911 kJ/mol, with the perchlorates being five or six times as positive as the analogous nitrates [202]. 2-Amino-4, 5-dimethyl tetrazolium perchlorate had a much higher melting point,  $T_d$ , and  $\Delta H_f$  than 1-amino-4, 5-dimethyltetrazolium perchlorate (413 vs. 324 K = 140 vs. 51 °C; 511 vs. 455 K = 238 vs. 182 °C, and 911 vs. 539 kJ/mol). This may correlate somewhat with the extent of the hydrogen bonding. Perchlorates had higher values than nitrates for all properties studied ( $T_m$ ,  $T_d$ ,  $d$ ,  $\Delta H_f$ ). One of the tetrazolium nitrates melted at <298 K (<25 °C) and only three of the salts melted at <373 K (<100 °C).

Several nitrogen-rich salts of 2-methyl-5-nitraminotetrazole were synthesized and characterized, with a particular focus placed on their properties as new energetic materials [908]. The triaminoguanidinium and diaminouronium salts especially showed promise as RDX replacements. Both demonstrated good performances, appropriate stabilities, facile synthesis, and moderate sensitivities, which are the main demands for a new energetic filler. 2-Methyl-5-nitraminotetrazole was

formed by the nitration of 2-methyl-5-aminotetrazole. 2-Methyl-5-aminotetrazole was obtained via an improved synthesis starting from sodium 5-aminotetrazolate, which was methylated with dimethyl sulfate in dimethyl formamide, producing 2-methyl-5-aminotetrazole in 29% yield. Nitrogen-rich salts such as guanidinium, 1-aminoguanidinium, 1,3-diamino-guanidinium, 1,3,5-triamino-guanidinium, azido-formamidinium, hydrazinium, and diaminouronium 2-methyl-5-nitraminetetrazolate were prepared by facile deprotonation or metathesis reactions.

Eight energetic salts based on 1-methoxy-5-nitroiminotetrazole, that was obtained by nitration of 1-methoxy-5-aminotetrazole, were synthesized [909]. Guanidinium, aminoguanidinium, diaminoguanidinium, triaminoguanidinium, carbonydiazidinium, 3-amino-1,2,4-triazolium, 4-amino-1,2,4-triazolium, and 3,5-diamino-1,2,4-triazolium 1-methoxy-5-nitroiminotetrazolate salts were prepared, purified, and characterized by vibrational spectroscopy (IR, Raman), multi-nuclear ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{15}\text{N}$ ) NMR spectroscopy, elemental analysis, and single-crystal XRD. The HOFs and detonation properties (pressure and velocity) were calculated. Thermal stabilities were measured by DSC and the sensitivities toward impact and friction were determined by BAM test methods.

1-Methyl-5-aminotetrazole (**4**) (MAT) can easily be protonated by strong acids such as nitric acid or perchloric acid, yielding 1-methyl-5-aminotetrazolium nitrate (**4a**) or 1-methyl-5-aminotetrazolium perchlorate (**4b**) [910]. Methylation, rather than protonation, of **4** with iodomethane followed by the exchange of the iodide (**5a**) for nitrate (**5b**), perchlorate (**5c**), azide (**5d**), or dinitramide (**5e**) yielded a series of energetic dimethylated aminotetrazolium salts. In all cases, stable salts were obtained and characterized by vibrational (IR, Raman) spectroscopy, multi-nuclear NMR spectroscopy, mass spectrometry, and elemental analysis and structure determination was carried out by XRD. Compounds **4a**, **4b**, and **5c** crystallized in the monoclinic space group  $P2_1n$ , whereas compounds **5b** and **5e** crystallized in the orthorhombic space group  $P2_12_12_1$  and **5d** in the orthorhombic  $Fddd$ . Safety testing (impact, friction, and electrostatic sensitivity) and thermal stability measurements (DSC) showed that all exhibited good thermal stabilities (decomposition above 423 K = 150 °C). The constant volume energies of combustion ( $\Delta U_{\text{comb}}$ ) of **4a**, **5b**, **5d**, and **5e** were determined experimentally using oxygen bomb calorimetry and found to be -10.5 kJ/g = -2.51 kcal/g, -13.3 kJ/g = -3.19 kcal/g, -18.8 kJ/g = -4.5 kcal/g, and -10.7 kJ/g = -2.57 kcal/g, respectively. From the experimentally determined density, the chemical composition and energies of formation (back-calculated from the heats of combustion), detonation pressures and velocities of **4a** (8100 m/s, 25.6 GPa), **5b** (7500 m/s, 20.2 GPa), **5d** (8200 m/s, 21.7 GPa), and **5e** (7500 m/s, 21.2 GPa) were predicted using the EXPLO5 code. The enthalpies of formation of the coordination compounds of perchlorates of Cu, Co, Zn, and Cd with 1,5-diaminotetrazole were calculated from the heats of solution of these salts in water [911–914].

Several energetic salts were synthesized via the quaternization of azido or the nitro derivatives of substituted tetrazoles by reaction with nitric or perchloric acid (or

iodomethane followed by metathesis reaction with silver nitrate or silver perchlorate) [328]. Most of the salts exhibited good thermal stabilities and low melting points. The heat of combustion energies was measured in an oxygen bomb calorimeter, and the standard molar enthalpies of formation were derived from the heat of combustion data.

Hydroxylammonium 2-dinitromethyl-5-nitrotetrazolate was synthesized via neutralization reaction with hydroxylamine and 2-dinitromethyl-5-nitrotetrazole and its properties were characterized by FTIR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR,  $^{15}\text{N}$  NMR, elemental analysis, and DSC [915]. The detonation velocity and detonation pressure of hydroxylammonium 2-dinitromethyl-5-nitrotetrazolate were calculated by DFT and K-J equation. The peak temperature of the DSC curve at a heating rate of  $10^\circ\text{C}/\text{min}$  was 418.4 K ( $145.3^\circ\text{C}$ ). Its predicted detonation velocity, detonation pressure, and specific impulse are 9.240 km/s, 39.54 GPa, and  $2639.8 \text{ N s kg}^{-1}$ , respectively.

Substitutions on 5-methyl-1-aminotetrazole by trinitroethyl moiety and furazan ring increased the oxygen balance and improved the detonation properties [916]. The structures of both compounds were determined by XRD, and their thermal stability and explosive performance were also investigated.

Properties of three nitrogen-base salts of 3,5-dinitrotetrazole, ammonium 3,5-dinitro-1,2,4-triazolate, diaminoguanidinium 3,5-dinitro-1,2,4-triazolate, and triaminoguanidinium 3,5-dinitro-1,2,4-triazolate have been assembled in Table 38, along with properties of seven salts of 1-hydro-3-nitro-1,2,4-triazol-5-one (NTO) [547, 548].

## 14.7 Tri-Substituted Tetrazolium and Tetrazolate Salts

The initiation of decomposition of several tri-substituted tetrazolium salts was studied by CRT at around 573 K ( $300^\circ\text{C}$ ) using rapid-scan FTIR spectroscopy and TOF mass spectrometry to identify the products evolved from samples subjected to heating rates of about 2000 K/s [917]. The compounds studied included 2-amino-4,5-dimethyl-tetrazolium nitrate (2AdMTZN) and 1-amino-4,5-dimethyl-tetrazolium nitrate (1AdMTZN). Methyl nitrate ( $m/e = 77$ ) was visible in some FTIR spectra. The resultant nitrogen-rich amino-methyl-tetrazole ( $m/e = 99$ ) was found to decompose to form primarily molecular nitrogen and methyl isocyanide. Unlike the 2AdMTZ salts, the 1AdMTZ salts were found to initiate decomposition at lower temperatures by at least  $50^\circ\text{C}$ . Decomposition was found to proceed through three major pathways: formation of the corresponding methylated anion and 1-amino-5-methyl-tetrazole, formation of ammonia by the amino group, and expulsion of nitrogen from the tetrazole cation itself. 1-Amino-5-methyl tetrazole was found to rapidly decompose to form mainly ammonia and nitrogen.

The thermal decomposition of 1,5-diamino-4-methyl-1*H*-tetrazolium nitrate (**2b**), 1,5-diamino-4-methyl-1*H*-tetrazolium dinitramidate (**2c**) and 1,5-diamino-4-methyl-

1*H*-tetrazolium azide (**2d**) were investigated by TGA and DSC [918]. Mass spectrometry and IR spectroscopy were used to identify gaseous decomposition products. Decomposition in the cases of **2c** and **2d** appeared to be initiated by a proton transfer to form the corresponding acids  $\text{HN}_3$  and  $\text{HN}_3\text{O}_4$ , whereas, in the case of **2b**, a methyl group transfer to  $\text{MeONO}_2$  was observed as an initial process. The gaseous products after the exothermic decomposition were comparable and were in agreement with the possible decomposition pathways predicted for the corresponding compounds by way of proposed possible decomposition schemes. The onset of decomposition temperatures of **2b** and **2c** were significantly higher than those of **2d** and were supported by an evaluation of the values of the activation energy, according to the Ozawa and Kissinger method.

1,4-Dimethyl-5-aminotetrazolium 5-nitrotetrazolate was synthesized from 1,4-dimethyl-5-aminotetrazolium iodide and silver 5-nitrotetrazolate [919]. Both compounds were characterized using vibrational (IR and Raman) and multi-nuclear ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ,  $^{15}\text{N}$ ) NMR spectroscopy, elemental analysis, and single-crystal XRD. 1,4-Dimethyl-5-aminotetrazolium 5-nitrotetrazolate represents an example of an energetic material that contains both a tetrazole-based cation and anion. 1,4-Dimethyl-5-aminotetrazolium 5-nitrotetrazolate was hydrolytically stable with a melting point of 463 K (190 °C) (decomposition). The impact sensitivity was very low (30 J), and it was not sensitive towards friction (>360 N).

1,3-Dimethyl-5-amino-1*H*-tetrazolium 5-nitrotetrazolate (**5b**) was synthesized from 1,4-dimethyl-5-amino-1*H*-tetrazolium iodide (**5a**) and silver 5-nitrotetrazolate. Both compounds (**5a** and **5b**) were characterized using IR, Raman, and multi-nuclear  $^1\text{H}$ ,  $^{13}\text{C}$ , and  $^{15}\text{N}$  NMR spectroscopy, elemental analysis, and single-crystal XRD [920]. Salt **5a** crystallized in orthorhombic crystal shapes with space group *Pbca*, and unit cell parameters of  $a = 11.5016(4) \text{ \AA}$ ,  $b = 13.7744(5) \text{ \AA}$ ,  $c = 13.7744(5) \text{ \AA}$ ,  $V = 1638.2(1) \text{ \AA}^3$ ,  $Z = 8$ ,  $\rho = 1.955 \text{ g/cm}^3$ , whereas salt **5b** crystallized in monoclinic crystal shapes, space group *C1c*, with unit cell parameters of  $a = 14.5228(8) \text{ \AA}$ ,  $b = 5.0347(2) \text{ \AA}$ ,  $c = 13.7217(7) \text{ \AA}$ ,  $\beta = 112.11(1)^\circ$ ,  $V = 929.6(2) \text{ \AA}^3$ ,  $Z = 4$ ,  $\rho = 1.630 \text{ g/cm}^3$ . The sensitivity of **5b** to classical stimuli was determined by using standard BAM tests and its thermal stability was assessed by DSC measurements. In addition, its heat of combustion was determined by bomb calorimetry measurements. The EXPLO5 was used to calculate the detonation pressure ( $P$ ) and velocity ( $D$ ) of salt **5b** ( $P = 13.3 \text{ GPa}$  and  $D = 6379 \text{ m/s}$ ), as well as those of its mixtures with AN ( $P = 23.2 \text{ GPa}$  and  $D = 7862 \text{ m/s}$ ) and ADN ( $P = 29.6 \text{ GPa}$  and  $D = 8594 \text{ m/s}$ ). Compound **5b** is a hydrolytically stable solid with a high melting point (433 K = 160 °C). It is thermally stable up to 463 K (190 °C) with a very low sensitivity to friction (>360 N) and impact (>30 J) and has good performance in combination with an oxidizer.

*In-situ* high-pressure room temperature synchrotron XRD and IR micro-spectroscopy were used to examine the structural and vibrational properties and the equation of state of 1,4-dimethyl-5-aminotetrazolium 5-nitrotetrazolate crystals [921]. The X-ray measurements showed a smoothly varying pressure-volume relationship

to 20 GPa. However, the anisotropic ratios of the unit cell parameters revealed a discontinuity near 3.3 GPa, which can be attributed to an irreversible isostructural phase transition.

## 14.8 Other Neutral and Ionic Tetrazole Derivatives

### 14.8.1 Tetrazolylcarbamides

As part of a PhD thesis, the following compounds were prepared and characterized by IR spectra and elemental analysis [922]:

- 5-hydrazinotetrazolium hydrochloride
- 1-(5-tetrazolyl)-semicarbazide
- 4-(5-tetrazolyl)-semicarbazide
- *N*-(5-tetrazolyl)urea
- *N*-(5-tetrazolyl)urethane
- 5-tetrazolylammonium cyanate
- *N*-(5-tetrazolyl)carbamyl azide

5-Guanyl“amino”tetrazole,  $C_2H_5N_7$ , *N*-1*H*-tetrazol-5-yl-guanidine, 1-(1*H*-tetrazol-5-yl)-guanidine, 5-guanyltetrazole, CAS RN [66591-60-4] or [68134-09-8],  $M = 127.11$ , is a high nitrogen compound with 77.1% N. 5-Guanyl“amino”tetrazole is a reaction product of cyanamide and 5-aminotetrazole and it can be used in gas generators for the inflation of airbags [923, 924].

The nomenclature used by some authors for this compound seems to be illogical. While commonly called “5-guanylaminotetrazole,” the correct name would be 5-guanyltetrazole because the amino group in 5-AT has been replaced by a guanyl group. As the amino group is no longer there, “amino” should not be part of the name of this compound. Below we have used a strikethrough type font to indicate that the word amino should not be there. The molecular structures of these two compounds are shown here for comparison.

5-Guanylaminotetrazole  $C_2H_6N_8$

5-Guanyltetrazole  $C_2H_5N_7$

The enthalpy of formation of 5-guanylamino-tetrazole is  $+255 \text{ cal/g} = 32.4 \text{ kcal/mol} = +135.6 \text{ kJ/mol}$  and the density is  $0.0509 \text{ lb/in.}^3 = 1.409 \text{ g/cm}^3$ .

The thermal stability of 5-guanylamino-tetrazole was evaluated by DTA-TGA. In a high-temperature deterioration test, the weight loss of the material was only 0.2% when heated for 400 h at 383 K, and neither discoloration nor deterioration in appearance was observed. In addition, 5-guanylamino-tetrazole was found to be insensitive to impact and friction. The combustion of a stoichiometric  $\text{Sr}(\text{NO}_3)_2$ /5-guanylamino-tetrazole mixture indicated that the mixture had excellent combustion properties and generated sufficient gas to inflate airbags.

5-guanylamino-tetrazole also forms a nitrate salt with nitric acid,  $\text{C}_2\text{H}_5\text{N}_7 \cdot \text{HNO}_3$ ,  $\text{C}_2\text{H}_6\text{N}_8\text{O}_3$ ,  $M = 190.12$ . Chemical Abstracts called this guanidine, 1*H*-tetrazol-5-yl-, mononitrate; CAS RN [66591-61-5]. This compound has been patented as a nitrogen source for fire extinguishers [925, 926]. The enthalpy of formation of 5-guanylamino-tetrazolium nitrate is  $+95 \text{ cal/g} = +18.06 \text{ kcal/mol} = +75.6 \text{ kJ/mol}$  and the density is  $0.0591 \text{ lb/in.}^3 = 1.636 \text{ g/cm}^3$  [61].

The crystal structure and an improved synthetic procedure for the synthesis of 1-(2*H*-tetrazol-5-yl)guanidine and 1-(2*H*-tetrazol-5-yl)guanidinium nitrate have been described in [927]. The compounds were structurally characterized by spectroscopic (FTIR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR) and elemental analysis. The molecular structure of tetrazolylguanidinium nitrate crystals was obtained from low-temperature single-crystal XRD. This salt crystallized as its hemihydrate in the orthorhombic space group *Fdd2*, with a crystal density of  $1.69 \text{ g/cm}^3$ . The molar enthalpy of formation of  $-281.7 \text{ kJ/mol}$  of the hemihydrate  $\text{C}_2\text{H}_7\text{N}_8\text{O}_{3.50}$  was calculated from the heat of combustion, however, this number is different from the number for the anhydrous salt listed in [61]. Another high-nitrogen compound is bis-triaminoguanidinium 5,5'-azotetrazolate.

#### 14.8.2 Other Tetrazole Compounds with C—C Linkages

1,1,3,3-Tetra(1*H*-tetrazol-5-yl)propane (TPP) is a propane chain with two tetrazole rings attached at each end. TTP can be synthesized by the reaction of propane-1,1,3,3-tetracarbonitrile with sodium azide in the presence of zinc bromide. The onset of the decomposition of TPP is at  $549 \text{ K} = 276^\circ\text{C}$ . Its predicted enthalpy of formation is  $1045 \text{ kJ/mol}$ . The reactions of TTP with four molar equivalents of imidazole, 4-nitroimidazole, 4-amino-4*H*-1,2,4-triazole, 1,2,4-triazole, 3-amino-1,2,4-triazole, 3,5-diamino-1,2,4-triazole, 3-nitro-1,2,4-triazole, 3,4-diaminofurazan, 5-aminotetrazole, melamine, 2,4,6-trinitroaniline, or guanidine in MeOH resulted in the formation of 1,1,3,3-tetra(1*H*-tetrazol-5-yl)propane-based tetraanionic energetic salts. The structures of these 12 salts were determined by  $^1\text{H}$  and  $^{13}\text{C}$  NMR, IR, MS, and elemental analysis [928]. All of these compounds showed good thermal stabilities above  $453 \text{ K} = 180^\circ\text{C}$ , as confirmed by TGA-DTA. Densities, HOFs, and detonation properties were calculated.

1,4-Dihydro-5*H*-(dinitromethylene)-tetrazole, 5-(dinitromethylene)-1,4-dihydro-tetrazole,  $C_2H_2N_6O_4$ ,  $M = 174.075$  g/mol, can be synthesized from 1,1-diamino-2,2-dinitroethene (DADNE, FOX-7) by reaction with hydrazine. This forms aminohydrazino-dinitroethene as an intermediate, which can then be diazotized to form a tetrazole ring. The 1,4-dihydro-5*H*-(dinitromethylene)-tetrazole diammonium salt,  $C_2H_8N_8O_4$ ; MW 208.14; 53.8% N, was synthesized and structurally characterized by single-crystal XRD [929].

The calculated X-ray density is  $1.615 \text{ g/cm}^3$ . The onset of exotherm in the DSC heated at  $10 \text{ K/min}$  was  $437 \text{ K} = 164^\circ\text{C}$  with a peak at  $482 \text{ K} = 209^\circ\text{C}$ . The critical temperature of thermal explosion was  $455.8 \text{ K} = 182.7^\circ\text{C}$ . The molar heat capacity was  $301 \text{ J mol}^{-1} \text{ K}^{-1}$  at  $298 \text{ K}$ . The predicted detonation velocity was  $9100 \text{ m/s}$  and the detonation pressure was  $35.3 \text{ GPa}$ .

5-(1,2,4-Triazol-3-yl)tetrazoles with selected energetic moieties like nitro, nitrimino, and azido groups on the triazole ring make good energetic compounds and have been studied. To achieve the objective of a comparative study on the influence of those variable energetic moieties on structural and energetic properties, a complete characterization (including IR, Raman, NMR, and XRD) was conducted [263, 930]. The standard enthalpies of formation were calculated for all compounds and revealed high positive HOF for each one. The calculated detonation parameters were in the range of  $8000 \text{ m/s}$ . As expected, the measured impact and friction sensitivities, as well as the decomposition temperatures, strongly depended on the energetic moiety on the triazole ring.

Similar compounds can be made where the 1-position of the tetrazole ring carries a hydroxyl group. For example, three 5-(1,2,4-triazol-C-yl)tetrazol-1-ol compounds with selected energetic moieties including nitrimino, nitro, and azido groups on the triazole ring were synthesized and characterized by IR, NMR, MS, XRD, and DSC [263, 931]. The detonation parameters were calculated and compared to RDX. The sensitivities towards impact, friction, and electrostatic discharge were determined by experiments.

N—C bonded (non-bridged) 5-(1,2,3-triazol-1-yl)tetrazoles can be synthesized by the Cu(I)-catalyzed 1,3-dipolar azide-alkyne cycloaddition click reaction using 5-azido-*N*-(propan-2-ylidene)-1*H*-tetrazole [932]. For example, the click reaction in the presence of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  and Na ascorbate at  $338\text{--}343 \text{ K}$  ( $65\text{--}70^\circ\text{C}$ ) for 48 h in  $\text{CH}_3\text{CN}/\text{H}_2\text{O}$  co-solvent was found to be limited to only terminal alkynes that have

EWG,  $\text{CF}_3\text{C}\equiv\text{CH}$ , and  $\text{SF}_5\text{C}\equiv\text{CH}$ , giving rise to isopropylidene-[5-(4-trifluoromethyl-1,2,3-triazol-1-yl)tetrazol-1-yl]amine and isopropylidene-[5-(4-pentafluorosulfanyl-1,2,3-triazol-1-yl)tetrazol-1-yl]amine. When carried out under conditions using CuI and 2,6-lutidine as catalysts at 273 K (0 °C) for 13 h in  $\text{CHCl}_3$ , the reaction was versatile toward all alkynes, even those with electron-donating groups. HOFs, detonation pressures, detonation velocities, and impact sensitivities were reported for these 5-(1,2,3-triazol-1-yl)tetrazoles.

Several metal and nitrogen-rich salts of 5-(5-azido-1*H*-1,2,4-triazol-3-yl)tetrazol-1-ol, 5-(5-azido-1*H*-1,2,4-triazol-3-yl)-1-hydroxy-tetrazole,  $\text{C}_3\text{H}_2\text{N}_{10}\text{O}$ , AzTTO, including Ag, Cu(I), Cu(II), K, Cs, ammonium, hydrazinium, guanidinium, and aminoguanidinium were prepared and characterized by IR, NMR, MS, DSC, and XRD [274]. The sensitivities towards impact, friction, and ESD were determined according to BAM standards, thereby revealing most of the metal salts to be highly sensitive and the nitrogen-rich salts to be mostly insensitive. The metal salts were tested as candidates for primary explosives.

5-(5-Azido-1*H*-1,2,4-triazol-3-yl)tetrazol-1-ol

*N*-trinitroethyl-substituted mono-, bis-, and tri-5-aminotetrazoles were obtained by reacting primary amines with *in-situ* generated cyanogen azide, followed by the trinitroethyl functionalization that involved the condensation of a hydroxymethyl intermediate (prepared by a reaction with formaldehyde) with trinitromethane [933]. These compounds were then characterized by NMR, IR, elemental analysis, DSC, and XRD. The HOFs were calculated with Gaussian 03 and then combined with experimental densities to calculate the predicted detonation pressures and velocities.

### 14.8.3 Tetrazolone

5-Hydroxytetrazole is a tautomeric form of tetrazolone-5, 1,4-dihydropyridine-5-one,  $\text{CH}_2\text{N}_4\text{O}$ , CAS RN [16421-52-6],  $M = 86.05$  g/mol.

Tautomeric structures of tetrazolone-5

Tetrazolone-5 (5-oxotetrazole) can be prepared by diazotization of 5-aminotetrazole in the presence of  $\text{CuSO}_4$ . Tetrazolone-5 can be isolated after removing the copper in the form of  $\text{CuS}$  and the sulfate as  $\text{BaSO}_4$ . Because of the explosive nature of the tetrazole diazonium cation, the diazotization should be carried out in dilute sulfuric acid at  $0^\circ\text{C}$  with a ratio of water/diazonium salt of approximately 1000/1. The enthalpy of formation of 5-hydroxytetrazole = tetrazolone-5 is  $-17\text{ cal/g} = -1.463\text{ kcal/mol} = -6.12\text{ kJ/mol}$ . The density is  $1.699\text{ g/cm}^3$ . Tetrazolone-5 has two acidic protons and can therefore be doubly deprotonated. Only strong or medium-strong bases like guanidine or triaminoguanidine can deprotonate tetrazolone. Only the single deprotonated salts were synthesized in this study. The following numbers refer to the compound numbers in that study. Seven nitrogen-rich salts, guanidinium (**2**), aminoguanidinium (**3**), diaminoguanidinium (**4**), triaminoguanidinium (**5**), ammonium (**6**), hydrazinium (**7**), and hydroxylammonium (**8**) were prepared by facile deprotonation or metathesis reactions [934]. All compounds were characterized by low-temperature single-crystal XRD. They crystallized in common space groups with densities ranging from  $1.554$  to  $1.625\text{ g/cm}^3$ . Salts were characterized by IR, Raman, NMR, elemental analysis, and DSC. The HOFs were calculated by quantum mechanical methods. With these values and the X-ray densities, several detonation parameters were calculated. The salts of tetrazolone have calculated detonation velocities between  $7257\text{ m/s}$  (**2**) and  $9034\text{ m/s}$  (**8**). The sensitivities (impact, friction, and electrical discharge) were tested by standard BAM methods. Tetrazolone and its salts are quite insensitive explosives with decomposition points between  $447\text{ K} = 174^\circ\text{C}$  (**5**) and  $512\text{ K} = 239^\circ\text{C}$  (**1**). The thermal decomposition of 5-hydroxytetrazole was investigated [935].

#### 14.8.4 Azidotetrazole Derivatives

The treatment of triaminoguanidinium chloride with two equivalents of sodium nitrite under acidic conditions, followed by the cyclization with stoichiometric amounts of either sodium hydroxide solution or solid sodium carbonate, yielded 1-amino-5-azidotetrazole, 5-azido-1-diazidocarbamoyltetrazole, and 1-(aminoazido-carbamoyl)-5-azidotetrazole [936]. These three compounds have been characterized using Raman, IR, NMR spectroscopy, mass spectrometry, XRD, and DSC. The sensitivity values obtained from measurements showed an extremely high sensitivity toward mechanical and thermal stimuli.

Base-catalyzed activation of the C–F bond in trifluoromethylazo-substituted cyclic and acyclic alkanes provides a route to di-substituted azidotetrazoles. For example, the reaction of 1,2-bis(trifluoromethylazo)ethane with four equivalents of  $\text{NaN}_3$  gave the alkyl-bridged bis(5-azido-1*H*-tetrazol-1-yl)-1,2-dimine, also called *N,N'*-bis(5-azido-1*H*-tetrazol-1-yl)-1,2-diiminoethane, with 75% yield [937].

*N,N'*-bis(5-azido-1*H*-tetrazol-1-yl)-1,2-diiminoethane

There are many carbon-nitrogen compounds with high nitrogen content that are of interest as gas generant ingredients. One of them was theorized to be an open-chain compound called tetraazido-2,3-diazabuta-1,3-diene [which is also called isocyanogen tetraazide or *N*-(diazidomethylene)-carbonohydrazonic diazide], CAS RN [67880-23-3] with the gross formula  $C_2N_{14}$ . For a while, it was not certain if  $C_2N_{14}$  existed in an open-chain (f) or a ring-closed form.

The binary CN compounds demonstrated here are: a.) dicyanogen, b.) tetraazido-methane, c.) triazidotriazine, d.) diazidotetrazine, e.) tetraazidoazotriazine (TAAT) and f.)  $C_2N_{14}$  (open chain form).

The synthesis of the closed form of 1-diazidocarbamoyl-5-azidotetrazole, 2-(5-azidotetrazol-1-yl)-1,3-diaza-guanidine,  $C_2N_{14}$ , CAS RN [1306278-47-6],  $M = 220.115$  g/mol, was discovered in 2011 while it was being synthesized by the diazotization of triaminoguanidinium chloride in water with two equivalents of sodium nitrite [938]. A suggested mechanism of this reaction is:

1-Diaزيدocarbamoyl-5-azidotetrazole, *N*-(5-azido-1*H*-tetrazol-1-yl)-carbonimidic diazide, CAS RN [1306278-47-6],  $\text{C}_2\text{N}_{14}$ , can be obtained as a colorless crystalline solid after recrystallization from diethyl ether. It has a melting point of 351 K = 78 °C and decomposition starts at 383 K = 110 °C. Single crystals of 1-diaزيدocarbamoyl-5-azidotetrazole suitable for XRD were obtained via recrystallization from diethyl ether. 1-Diaزيدocarbamoyl-5-azidotetrazole has a density of 1.723 g/cm<sup>3</sup> and an enthalpy of formation of +1495 kJ/mol. It crystallizes in the orthorhombic space group *Pbcn* with a cell volume of 1697.6(2) Å<sup>3</sup>. The sensitivity of  $\text{C}_2\text{N}_{14}$  is beyond our capabilities of measurement because, at the smallest possible loading in shock and friction tests, it still leads to explosive decomposition. The shock and friction sensitivity of 1-diaزيدocarbamoyl-5-azidotetrazole no doubt lies well under the limits of 0.25 J in impact. The 1 N in friction sensitivity can be experimentally determined.

Later investigations proved that the open-chain form tetraazido-2,3-diazabuta-1,3-diene exists only as a short-lived intermediate and cyclicizes early at 253 K (−20 °C) to the more stable 1-diaزيدocarbamoyl-5-azidotetrazole [939].  $\text{C}_2\text{N}_{14}$  would make a good propellant, source of nitrogen, or explosive had it not had high sensitivity.

A theoretical study that included the performance prediction of the high-nitrogen compound  $\text{C}_2\text{N}_{14}$  performed a computational optimization of four theoretically possible isomers using a DFT method. The vibration frequencies of four isomers were analyzed at the same ground level [940]. The frontier orbital energy difference, theoretical density, enthalpy of formation, theoretical detonation velocity, and detonation pressure of the four isomers were evaluated. The results showed that the MO energy difference of the four isomers is 359, 434, 553, and 553 kJ/mol, respectively. The theoretical densities are 1.682, 1.809, 1.742, and 1.743 g/cm<sup>3</sup>, respectively. The enthalpies of formation are 1521, 1435, 1404, and 1404 kJ/mol, respectively. The theoretical detonation

velocities (detonation pressures in parentheses) are 8405 m/s (30.63 GPa), 8725 m/s (34.52 GPa), 8454 m/s (31.68 GPa), and 8456 m/s (31.70 GPa), respectively.

#### 14.8.5 Thermal Decomposition of Bi- and Multi-Substituted Tetrazoles

Crystalline 1*H*-tetrazole is very sensitive to impact (<4 J) but not to friction. In contrast, the (substituted) guanidinium salts have sensitivities much lower than those of RDX and HMX. The gas products from rapid thermolysis of aminotetrazoles can affect the burn rate of a composite propellant containing these chemicals [941]. 1,5- and 2,5-diaminotetrazole decomposes by two competitive reactions. One reaction gives HCN, NH<sub>3</sub>, and N<sub>2</sub> and the other gives NH<sub>2</sub>CN, NH<sub>3</sub>, and N<sub>2</sub>. The observed product ratios reflect the competition of these two reactions. No melamine-like cyclic azines form from the self-reaction of NH<sub>2</sub>CN because NH<sub>2</sub>CN is rapidly evolved from the sample and diluted into the cool Ar atmosphere of the cell. Non-competitive decomposition reactions occurred with 1- and 5-aminotetrazole. 1-AT produced HCN, NH<sub>3</sub>, and N<sub>2</sub>, while 5-AT produced HN<sub>3</sub> and NH<sub>2</sub>CN. However, at 5.86 MPa (850 psia) of Ar, 5-AT produced melamine-like cyclic azine and NH<sub>4</sub>N<sub>3</sub> aerosols. 5-AT was the only aminotetrazole that produced melamine-like products upon heating of the unconfined material.

In a review of the literature on the thermal decomposition of tetrazole derivatives, it was shown that there are two radically different pathways of the tetrazole cycle fragmentation that leads to the formation of dinitrogen or azides [942]. The elimination of dinitrogen from 2,5-di-substituted tetrazoles resulted in a nitrilimine. The elimination of dinitrogen from 1,5-di-substituted tetrazoles led to the formation of nitrene. The stabilization of active intermediate products depends on the chemical properties of the substituents and the conditions under which the process is carried out. This leads to a wide spectrum of final products for the thermal decomposition of multi-substituted tetrazoles. Kinetic studies of the thermolysis of tetrazoles showed that the mechanism of heterocycle fragmentation can vary with varying temperatures. The elimination of dinitrogen from tetrazoles is usually preceded by a high-polarity transition state.

DFT computations and a semi-empirical quantum chemical computation were performed on a series of tetrazole derivatives and their metal salts to investigate the relationship between the relative order of impact sensitivity and activation energy of thermal decomposition [943]. The results showed that the relative order of sensitivity for the tetrazole derivatives compounds can be predicted by examining the activation energy for breaking down the weakest link of the tetrazole ring.

The combustion behavior and thermal decomposition kinetics of 2-methyl-5-nitrotetrazole were studied by measuring temperature profiles in the combustion wave of a compressed pellet with thin tungsten-rhenium thermocouples embedded in the strands [944]. Analyses of gaseous and condensed combustion products and the thermolysis products by GC, IR-, UV-, and mass-spectrometry showed that the combustion of the endothermic molecule containing the oxidizing nitro group proceeded in

the gas phase. The 2-methyl-5-nitrotetrazole monomolecular decomposition reaction was rate-controlling and determined the burning rate.

Ionic salts containing 5-amino-2-methyl- and 5-amino-1,3-dimethyltetrazolium cations with energetic anions (perchlorate, nitrate, azide, and dinitramide) have been synthesized and characterized using vibrational and  $^{15}\text{N}$  NMR spectroscopy and XRD [945]. Unexpectedly, salts based on the asymmetric 5-amino-1,3-dimethyltetrazolium cation had higher densities than analogue compounds containing the isomeric 5-amino-1,4-dimethyltetrazolium cation. This was regardless of the lower symmetry of the former. This can be attributed to secondary interactions between the cation and anion and is reflected in the higher detonation parameters of these compounds. This represents a new class of nitrogen-rich, high-performing materials with low sensitivity and good potential for energetic applications.

## 14.9 Bitetrazole and Bitetrazole Derivatives

Linking two tetrazole rings can be done in multiple ways. The most common method is via a C—C bond at the 5-position, which gives 5,5'-bitetrazole, also known as 5,5'-bistetrazole, 5-tetrazolyl-tetrazole(5), ditetrazole, 5-(1*H*-tetrazol-5-yl)-1*H*-tetrazole, CAS RN [2783-98-4],  $\text{C}_2\text{H}_2\text{N}_8$ ,  $M = 138.09$ ; a high-nitrogen compound with 81.1% N. These compounds are commonly called bistetrazole although the more correct name would be bitetrazole. For instance, the compound formed by connecting two benzene rings is correctly called *biphenyl* and not *bisphenyl*. Therefore, the correct name, as per Chemical Abstract IUPAC conventions, is 5,5'-bi-2*H*-tetrazole, CAS RN [2783-98-4].

5,5'-Bi-2*H*-tetrazole CAS RN [2783-98-4]

5-(1*H*-tetrazol-5-yl)-5*H*-tetrazole CAS RN [634151-41-0]

Alternate names are 5,5'-bi-1*H*-tetrazole and 5,5'-bis-1*H*-tetrazole. The location of the hydrogen atom(s) may vary depending on the conditions during synthesis. In addition to linking two tetrazole rings directly with a C—C linkage at the 5-position, there are less common isomers with a C—N linkage or an N—N linkage between the two rings.

The isomer is 5-(tetrazol-1-yl)-2*H*-tetrazole, also called 1-(1*H*-tetrazol-5-yl)tetrazole or 2'*H*-1,5'-bitetrazole, CAS RN [103518-52-1]; the linkage is from atom five on the first ring to atom one on the second ring.

1-(2*H*-Tetrazol-5-yl)-1*H*-tetrazole, CAS RN [103518-52-1]

If the connection is from the N1 nitrogen atom to another N1 nitrogen atom on the other ring, the resulting 1,1'-bitetrazole, also called 1-(tetrazol-1-yl)tetrazole, CAS RN [1316336-11-4], is an isomer to the more common 5,5'-bitetrazole.

1,1'-Bitetrazole, CAS RN [1316336-11-4]

In addition to linking two tetrazole rings directly with a C—C, C—N, or N—N linkage, there are also azotetrazole compounds with an —N=N— bridge and hydrazotetrazole compounds with an —NH—NH— bridge between the two rings. There are also secondary amines with two tetrazolyl rings linked by an imino —NH— group. These will be discussed in a later section in this chapter. Bitetrazole derivatives are nitrogen-rich, high-performing, insensitive energetic compounds that are suitable as sources of nitrogen in gas generants for inflators [946].

#### 14.9.1 Preparation of Bitetrazole and Bitetrazole Derivatives

Bitetrazole is rarely used but is most often applied in its salt form, especially as bitetrazolate salts with nitrogen-rich cations. A common bitetrazolate salt is the diammonium salt that can be made using hydrazine hydrate and cyanogen as starting materials [947–951]. Diammonium 5,5'-bi-1*H*-tetrazolate can be prepared by reacting cyanogen (dicyan), sodium azide, and ammonium chloride in water as a reaction medium. The first step is using oxaldiimidic acid dihydrazide that is obtained by the reaction of hydrazine hydrate with cyanogen. Oxalimidic acid dihydrazide is synthesized by reaction of dicyanogen and hydrazine hydrate in a polar solvent at 263 to 323 K (–10 to 50 °C) for 2–30 h using a molar ratio of hydrazine hydrate to cyanogen of 2.5–3.5. This yields a crystalline product that is then dissolved in an aqueous solution of a weak acid such as acetic acid. The next step is the dropwise adding of an aqueous solution of sodium nitrite to form an azide and to effect the cyclization reaction by

heating. 5-Cyano-1*H*-tetrazole is an intermediate in this reaction. The bitetrazole is first deprotonated by sodium hydroxide and then the sodium salt is converted to the less soluble ammonium salt by the addition of ammonium chloride. This process is advantageous as the 5,5'-bi-1*H*-tetrazole diammonium salt is synthesized and the precipitated crystals that are produced as a result are simply isolated by filtration to obtain the 5,5'-bi-1*H*-tetrazole diammonium salt, thus maintaining a yield better than 90%. The 5,5'-bi-1*H*-tetrazole diammonium salt, which has low toxicity and is easy to handle, is used as a gas-generating agent for airbags. Depending on the method chosen, cyanogen can either be prepared and isolated in an additional pre-step and treated with either sodium azide or hydrazoic acid or it can be generated *in-situ* from sodium cyanide and manganese dioxide as the oxidizing agent under acidic conditions and be further treated with sodium azide.

Barium 5,5'-bitetrazolate and several similar barium salts were obtained by metathesis reaction between bitetrazolium and similar sulfates and soluble barium salts [952].

Both the sodium salt and the potassium salts are useful intermediates in the synthesis of other bitetrazolate salts. The synthesis of bitetrazole, potassium bitetrazolate, guanidinium bitetrazolate, and aminoguanidinium bitetrazolate by way of the intermediate product manganese bitetrazolate was improved by adding acetic acid and cupric sulfate [953]. Potassium bitetrazole was formed by high-temperature substitution reactions between manganese bitetrazolate, and potassium carbonate. Bitetrazole carbonate, guanidinium carbonate, or aminoguanidinium bicarbonate react directly to produce guanidinium bitetrazolate and aminoguanidinium bitetrazolate. The products were characterized by DSC-TGA, elemental analysis, IR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, and MS methods. The shock sensitivity test results showed that the sensitivity of bitetrazole itself is higher than that of bitetrazolate salts.

5,5'-Bitetrazole and its salts can be prepared by reaction of azides with cyanogen in the presence of Lewis acids, organic carboxylic acids, or alkylsulfonic acids. Thus, the reaction of sodium azide with cyanogen in acetonitrile in the presence of  $\text{AlCl}_3$  gives 5,5'-bitetrazole with a yield of 75.6% [954].

The diammonium salt  $\text{C}_2\text{H}_2\text{N}_8 \cdot 2\text{NH}_3$ ; 5,5'-bi-2*H*-tetrazole, ammonium salt (1:2); CAS RN [944393-83-3], is a useful high-nitrogen compound. Most patents deal with the diammonium salt of bitetrazole, but if the pH of a solution of the diammonium salt is acidified with sulfuric acid to pH <4.5, one can isolate the monoammonium salt as well [955].

5-(Tetrazol-1-yl)-2*H*-tetrazole or 1,5-bitetrazole can be synthesized by the cyclization of 5-amino-1*H*-tetrazole, sodium azide, and triethyl orthoformate in glacial acetic acid [956]. A methyl-substituted derivative of 1,2-methyl-5-(tetrazol-1-yl)tetrazole (**2**) can be obtained by this method by starting from 5-amino-2-methyl-tetrazole instead of 5-AT. Selected salts of 1,5'-bitetrazole with nitrogen-rich and metal (alkali and transition metal) cations, including hydroxylammonium, triaminoguanidinium, copper(I), and silver, as well as copper(II) complexes were prepared and characterized by IR, Ra-

man, NMR spectroscopy, MS, DSC, and single-crystal XRD. Their sensitivities towards physical stimuli (impact, friction, ESD) were determined according to BAM standard test methods. Energetic performance parameters (detonation velocity, pressure, etc.) were calculated with the EXPLO5 program, based on predicted HOFs derived from computed enthalpies. Other methods for the preparation of bitetrazole are described in [957, 958]. There are many energetic bicyclic azolium salts [109, 180].

Both 1,1'-diamino-5,5'-bitetrazole and 1,2'-diamino-5,5'-bitetrazole have been prepared by the amination of the parent anion with *O*-tosylhydroxylamine and characterized by XRD, NMR, IR, Raman, mechanical impact, and electrostatic discharge sensitivity measurement. Their explosive performances were calculated using the EXPLO5 computer code [318]. Instead of amino groups, hydrazino groups can be attached to one or both rings in bitetrazole, resulting in 5,5'-hydrazinobitetrazole, which can form salts with alkali metals [959].

The nitrogen-rich energetic compound 5-(1*H*-tetrazolyl)-1-hydroxytetrazole, also known as 1-hydroxy-5-(1*H*-tetrazol-5-yl)tetrazole, was obtained in good yield via sodium 5-cyanotetrazolate sesquihydrate, 5-aminohydroximoyl tetrazole, 5-chlorohydroximoyl-tetrazole, and 5-azidohydroximoyl-tetrazole monohydrate [960].

5-(1*H*-Tetrazolyl)-1-hydroxytetrazole

It can be deprotonated twice by various bases. Several ionic derivatives such as bis(hydroxylammonium), bis(hydrazinium), bis(guanidinium), bis(aminoguanidinium), bis(ammonium), and diaminouronium 5-(1-oxidotetrazolyl)-tetrazolates were synthesized and characterized. All compounds were characterized by NMR, IR, Raman, mass spectroscopy, elemental analysis, DSC, and tested for impact, friction, and ESD sensitivity.

1,1'-Dinitramino-5,5'-bitetrazole and 1,1'-dinitramino-5,5'-azobitetrazole are extremely sensitive and powerful explosives [961]. Selected nitrogen-rich salts were prepared to adjust sensitivity and performance values. The compounds were characterized by XRD, IR and Raman spectroscopy, NMR, elemental analysis, and DTA/DSC. Calculated energetic performances based on calculated HOFs and X-ray densities supported the predicted high performances of the 1,1'-dinitramino-5,5'-bitetrazoles as energetic materials. Most of the compounds showed sensitivities in the range of primary explosives and, therefore, should only be handled with great care.

### 14.9.2 Physical Properties of Bitetrazole and Bitetrazole Derivatives

The predicted density of 5,5'-bitetrazole is  $1.593 \pm 0.06 \text{ g/cm}^3$  based on theoretical computations, but measured XRD density is  $\rho_{\text{X-ray}} = 1.738 \text{ g/cm}^3$ .

There are two different data sets offered for the enthalpy of formation in the PEPCODED.DAT database [61]:  $+1093 \text{ cal/g} = +150.9 \text{ kcal/mol} = +631 \text{ kJ/mol}$  and  $+797 \text{ cal/g} = 110.0 \text{ kcal/mol} = +460 \text{ kJ/mol}$ . However, it is not known which is correct. Neither one matches the experimentally determined HOF of  $+127.08 \pm 0.23 \text{ kcal/mol} = +531.7 \pm 0.96 \text{ kJ/mol}$ , which is somewhere between these two extreme values [962].

The enthalpy of formation of guanidinium 5,5'-bitetrazolate,  $\text{C}_3\text{H}_7\text{N}_{11}$ , MW 197.17, with 78.1% N, is  $+369 \text{ cal/g} = +72.7 \text{ kcal/mol} = +304 \text{ kJ/mol}$ . The density is  $0.0566 \text{ lb/in.}^3 = 1.567 \text{ g/cm}^3$ . The enthalpy of formation of tetramethylammonium bitetrazolate,  $\text{C}_6\text{H}_{13}\text{N}_9$ ,  $M = 211.23 \text{ g/mol}$ , is  $+118 \text{ cal/g} = +24.9 \text{ kcal/mol} = +104.3 \text{ kJ/mol}$ . The density is  $0.0488 \text{ lb./in.}^3 = 1.351 \text{ g/cm}^3$ . The X-ray crystal structure of 5,5'-bitetrazole at 130 K showed that 5,5'-bitetrazole exists as the 1*H*,1'*H*-tautomer and packs in chains held together by pairs of intermolecular hydrogen bonds [963]. It crystallized in the monoclinic space group  $P2_1/n$  with  $a = 4.945(1) \text{ \AA}$ ,  $b = 6.367(1) \text{ \AA}$ ,  $c = 8.491(1) \text{ \AA}$ ,  $\beta = 99.233(7)^\circ$ ,  $\rho_{\text{X-ray}} = 1.738 \text{ g/cm}^3$ , and  $Z = 2$ .

1,1'-Dihydroxy-5,5'-bistetrazole (1,1'-BTO) was synthesized using dichloro-glyoxime, sodium azide, and dimethyl formamide as primary materials and reacted with hydroxylammonium chloride to form dihydroxylammonium 5,5'-bistetrazole-1,1'-diolate (which is also known under its code name of TKX-50) with a yield of 73.2% [964]. There are strong inter- and intra-molecular hydrogen bonds in the solid crystal. These hydrogen bonds effectively improved the density of TKX-50 to  $1.918 \text{ g/cm}^3$ . Based on this density, detonation parameters were calculated as close to 9698 m/s, the detonation pressure was 42.4 GPa, the friction sensitivity was 120 N, and the impact sensitivity was 20 J. A method for the purity analysis of dihydroxylammonium 5,5'-bistetrazole-1,1'-diolate (TKX-50) using HPLC was established by optimizing the chromatographic conditions [965].

Following the synthesis, theoretical performance (sea-level  $I_{\text{sp}}$ ) of a composite modified double-base (CMDB) propellant, hydroxy-terminated polybutadiene (HTPB) propellant, nitrate ester plasticized polyether (NEPE) propellant, and GAP propellant containing dihydroxylammonium 5,5'-bistetrazole-1,1'-diolate (TKX-50) was calculated. It was found that the theoretical specific impulse of the TKX-50 propellant was  $2623.7 \text{ N s kg}^{-1}$ , which is  $6.5 \text{ N s kg}^{-1}$  higher than that of the RDX propellant [966]. TKX-50 would be a good replacement for RDX in CMDB propellants. When substituting TKX-50 for AP in HTPB propellants and AP and HMX in GAP propellants, similar improvements of theoretical specific impulses were predicted, also in comparison to HMX or CL-20 as replacements for AP [967].

Crystals of dihydroxylammonium 5,5'-bistetrazole-1,1'-diolate (HATO) were synthesized and characterized [891]. HATO exhibited excellent thermal stability. The decomposition temperature was 503.4 K (230.3°C), and the volume of released gas during a thermal stability test was 0.30 mL/g at 373 K (100°C) for 48 h. It had low mechanical

sensitivities; the explosion probabilities of impact sensitivity and friction sensitivity were 16 and 24%, respectively.

### 14.9.3 Chemical Properties of Bitetrazole and Bitetrazole Derivatives

There are many patents on the use of 5,5'-bitetrazolates of nitrogen-containing cations as gas generants in airbag inflators. 5,5'-Bitetrazole can give off one or two protons and form dibasic bitetrazolate salts with strong bases. It can also be protonated to form tetrazolium salts. The constants of proton detachment and the addition of protons for 5,5'-ditetrazole and of protonation of 1,1'-diphenyl-5,5'-bitetrazole in aqueous solutions were determined by spectrophotometric and potentiometric methods [968]. The aqueous  $pK_a$  values for the first and second ionizations (anion formation) of 5,5'-bitetrazole ( $R=H$ ) were 1.41 and 4.25; the first and second  $pK_{BH^+}$  values for protonation were -5.47 and -10.91.

5,5'-Bitetrazole starts decomposing soon after melting at  $563\text{ K} = 290^\circ\text{C}$ . The kinetic parameters of the thermal decomposition of tetrazole and 5,5'-bitetrazole in melts of neat substances and nitrobenzene solutions have been determined using a manometric method [732]. The proposed mechanism involved limiting stages of the monomolecular decomposition. This determines the observed rate of nitrogen formation, proceeding to the fast reversible transformation of the 1*H*- and 2*H*-forms and the reversible opening of the 2*H*-form. It is followed by the formation and subsequent cleavage of the corresponding intermediate diazo compound.

The alkaline earth metal (Be, Mg, Ca, Sr, Ba) salts of 5,5'-bitetrazole were prepared and characterized by low-temperature XRD, IR, Raman and NMR spectroscopy, elemental analysis, and DSC [969]. The Sr and Ba salts can be used in coloring pyrotechnical compositions and thus avoid the use of perchlorates, making the formulation more environmentally friendly.

Eight different salts formed from twice-deprotonated 5,5'-bitetrazole: ammonium (**1**), hydrazinium(1+) (**2**), hydroxylammonium (**3**), guanidinium (**4**), aminoguanidinium (**5**), diaminoguanidinium (**6**), triaminoguanidinium (**7**), and diaminouronium (**8**). The numbers refer to the compounds listed in Table 61. 5,5'-Bitetrazolate salts have been synthesized and characterized by single-crystal XRD, NMR, IR and Raman spectroscopy, and DSC [970]. The sensitivity towards impact, friction, and ESD was determined. Several propulsions and detonation parameters (e.g., heat of explosion, detonation velocity) were computed based on calculated HOFs and X-ray densities. Some select properties of these eight high-nitrogen compounds are summarized in Table 61.

Although the alkali metal bitetrazolates are of little interest as rocket propellants, they deserve to be studied as intermediates in the preparation of other bitetrazolate salts. For example, the monoammonium and the bisammonium bitetrazolates are useful gas generant ingredients. The alkali metal 5,5'-bitetrazolates of Li, Na, K, Rb, and Cs, the mono and bis-ammonium, and the mono- and bis(1-ethyl-3-methylimi-

Table 61: Calculated and measured properties of bitetrazolate salts of nitrogen-rich cations.

Data source: [970].

dazolium) salts of 5,5'-bitetrazole were synthesized and characterized by NMR and IR spectroscopy, elemental analysis, and combined TGA/DSC [971]. It is interesting to note that, in the IR spectra, all bands slowly shifted to lower wavenumbers when proceeding from lithium to cesium as counter ions with increasing ion radii. A distinct effect of the atomic weight of the counter ion on the lattice vibrations of the bitetrazolate ion could be observed. Bis(1-ethyl-3-methylimidazolium) 5,5'-bitetrazolate,  $C_{14}H_{22}N_{12}$ , is the first known ionic liquid derived from bitetrazole. It melts at just  $368\text{ K} = 95^\circ\text{C}$  and can, therefore, be classified as an ionic liquid. The decomposition of the substance follows at  $523\text{ K} = 250^\circ\text{C}$ . The monoammonium salt started to decompose at an onset temperature of  $555\text{ K} = 282^\circ\text{C}$  and the diammonium salt measured for direct comparison showed decomposition at  $563\text{ K} = 290^\circ\text{C}$ . Other 5,5'-bitetrazolate salts have been reported in [972].

#### 14.9.4 Bitetrazole Derivatives with Substituents on the Rings

The oxygen balance of bitetrazole derivatives can be improved by adding hydroxyl or nitro groups to the rings.

##### 14.9.4.1 1,1'-Hydroxyl-5,5'-Bitetrazole

1,1'-Hydroxyl-5,5'-bitetrazole, 1*H*,1'*H*-5,5'-bitetrazole-1,1'-diol, is an energetic compound that is more acidic than bitetrazole itself and can form a wide range of salts. The dihydroxylammonium salt of 1,1'-hydroxyl-5,5'-bitetrazole, which is also called dihydroxylammonium 5,5'-bi(s)tetrazole-1,1'-diolate, has been tested as a new insensitive but powerful explosive. It has been given the code name TKX-50.

Dihydroxylammonium 5,5'-bitetrazole-1,1'-diolate (TKX-50) and the intermediates 5,5'-bitetrazole-1,1'-diol dihydrate, 5,5'-bitetrazole-1,1'-diol dimethanolate, and dimethylammonium 5,5'-bitetrazole-1,1'-diolate were prepared and characterized by XRD, NMR, vibrational spectroscopy, DSC, mass spectrometry, and sensitivity tests [973]. TKX-50 outperforms all other recently developed explosive materials such as ONC and CL-20. It differs in that it is simple and cheap to prepare from commonly available chemicals. It is easily prepared, is exceedingly powerful, and possesses the required thermal insensitivity, low toxicity, and safety of handling to replace the most commonly used military explosive also, which is RDX.

The isomeric 5,5'-bi(2-hydroxytetrazole) can be prepared by oxidation of 5,5'-bitetrazole using commercially available Oxone (potassium peroxydisulfate) [974]. Once 5,5'-bi(2-hydroxytetrazole) became available with the necessary purity, the nitrogen-rich salts including ammonium, hydroxylammonium, guanidinium, aminoguanidinium, triaminoguanidinium, 5-aminotetrazolium, and aminonitroguanidinium could be prepared and characterized by XRD, NMR, vibrational spectroscopy, DSC, and MS, and compared to their 5,5'-bi(tetrazole-1-oxide) analogues. The impact, friction, and electrical spark sensitivities of all these compounds were measured and several detonation parameters, such as the detonation velocities

and detonation pressures, were also calculated based on calculated HOFs and the X-ray densities.

1*H*,1'*H*-5,5'-Bitetrazole-1,1'-diol was synthesized starting from glyoxal, which is converted to glyoxime after treatment with hydroxylamine [975]. The chlorination of glyoxime with Cl<sub>2</sub> gas in ethanol (and the subsequent chloro/azido exchange) yielded diazidoglyoxime. This was cyclized under acidic conditions (HCl gas in diethyl ether) to give 1*H*,1'*H*-5,5'-bitetrazole-1,1'-diol dihydrate. A large variety of nitrogen-rich salts of 1*H*,1'*H*-5,5'-bitetrazole-1,1'-diol such as diammonium, dihydrazinium, bis-guanidinium, bis(aminoguanidinium), diaminoguanidinium salt monohydrate, triaminoguanidinium salt monohydrate, 1-amino-3-nitroguanidinium salt dihydrate, diaminouronium salt monohydrate, bis(oxalyldihydrazidinium), oxalyldihydrazidinium salt dihydrate, 3,6-dihydrazino-1,2,4,5-tetrazinium, 5-aminotetrazolium, bis(5-amino-1-methyl-1*H*-tetrazolium) salt, bis(5-amino-2-methyl-2*H*-tetrazole) adduct, and 1,5-diaminotetrazolium salt were synthesized using Brønsted acid-base or metathesis reactions. All compounds were fully characterized by IR and Raman spectroscopy, NMR, elemental analysis, DSC, and XRD. The HOFs were calculated and several detonation parameters such as the detonation pressure, detonation velocity, explosion energy, and explosion temperature were computed. The sensitivities towards impact, friction, and ESD were tested using the BAM drop-hammer, a Peters friction sensitivity tester, as well as a small-scale ESD tester.

Hydroxylammonium 1,1'-dihydroxyl-5,5'-bistetrazolate has been developed as a solid propellant ingredient in China under the designation TKX-50 [976]. The performance of TKX in comparison to HMX or CL-20 as monopropellant under different pressures was calculated using a minimum free energy method. The performance of propellant formulations CL-20-CMDB and TKX-50-CMDB obtained by replacing HMX with CL-20 or TKX-50 was calculated under the standard condition ( $p_c:p_a = 70:1$ ). TKX-50 was predicted to have improved performance and, at pressures in the range 1–10 MPa, it has lower combustion temperature, higher characteristic velocity, and specific impulse than HMX. Its combustion products have lower average relative molecular mass than those of HMX. Using TKX-50 in CMDB propellant formulations increases specific impulses and it also effectively decreases smoke in the rocket motor exhaust plume.

1,1'-Dihydroxy-5,5'-bitetrazole (H2DHBT) was synthesized via substitution and cyclization using dichloroglyoxime as starting material [977]. Its DSC exothermic decomposition peak temperature was 504 K = 231 °C. The theoretical density of an optimized geometry of H2DHBT obtained by quantum chemical calculations was 1.789 g/cm<sup>3</sup>. The HOF of solid-state H2DHBT was +558.9 kJ/mol. The predicted detonation velocity and detonation pressure of H2DHBT using the K-J equation were 8475 m/s and 32.4 GPa, respectively. H2DHBT can be used as an energetic anion through the deprotonation of one or two of the hydroxyl groups.

In addition to the hydroxylammonium salt, the guanidinium salt of 1,1'-dihydroxy-5,5'-bitetrazole was also prepared and characterized [978]. Using

1,1'-dihydroxy-5,5'-bitetrazole and guanidinium carbonate as raw materials, guanidinium 1,1'-dihydroxy-5,5'-bitetrazolate (G2DHBT) was synthesized and characterized by NMR, IR, elementary analysis, and XRD. G2DHBT crystallized in monoclinic, space group  $P2_1/c$  crystals with  $a = 3.6477(14) \text{ \AA}$ ,  $b = 16.966(7) \text{ \AA}$ ,  $c = 9.546(4) \text{ \AA}$ ,  $\alpha = 90^\circ$ ,  $\beta = 97.465(6)^\circ$ ,  $\gamma = 90^\circ$ ,  $V = 585.8(4) \text{ \AA}^3$ ,  $Z = 2$ , and  $\rho_{\text{X-ray}} = 1.634 \text{ g/cm}^3$ . The thermal stability and the mechanical sensitivity of G2DHBT were tested by DSC and standard method GJB 772A-97, respectively. The solid-state HOF of G2DHBT was calculated using the CBS-4M method and found to be  $+387.69 \text{ kJ/mol}$ . The detonation parameters and performance as a monopropellant were predicted by using the K-J equation and the minimum free energy method, respectively. The DSC thermal decomposition peak was at  $562.9 \text{ K} = 289.8^\circ\text{C}$ . The 50% drop height was  $112.2 \text{ cm}$ , the detonation velocity was  $7202 \text{ m/s}$ , the detonation pressure was  $22.1 \text{ GPa}$ , and the specific impulse was  $1977 \text{ Ns/kg}$ .

Using dichloroglyoxime as raw material, dihydroxylammonium 5,5'-bitetrazole-1,1'-diolate was synthesized via substitution, cyclization, and metathesis reaction with a total yield of 81.7% [979]. Wet diazidoglyoxime was found to increase the operational safety and dilithium 5,5'-bistetrazole-1,1'-diolate (which has a high solubility in water) was used to increase the yield of the metathesis reaction. The properties of dihydroxylammonium 5,5'-bitetrazole-1,1'-diolate, such as thermal stability, mechanical sensitivity, morphology, particle size, and particle size distribution, were investigated. In the DSC, when heated at a rate of  $10 \text{ K/min}$ , the maximum of the exothermic peak was at  $249^\circ\text{C}$ . The standard volume of gas evolved during 48 h at  $373 \text{ K}$  was  $0.3 \text{ mL/g}$ . The drop weight impact sensitivity was 16% with a 10 kg drophammer, at 25 cm drop height, and 50% with a 5 kg drophammer at 100 cm drop height.

5-Aminotetrazolium 1'-hydroxy-1*H*,1'*H*-5,5'-bitetrazol-1-olate (5-ATHTO) was synthesized from glyoxal, hydroxylamine, and aminoguanidine carbonate at  $373 \text{ K}$  ( $100^\circ\text{C}$ ). With a reaction time of 5 h, the yield of 5-ATHTO was up to 86% [980]. The structure of 5-ATHTO was identified by NMR, IR, and MS. The thermal stability was analyzed by DSC and the compound decomposed at about  $513 \text{ K}$  ( $240^\circ\text{C}$ ), thus indicating good thermal stability. The theoretical density of 5-ATHTO was predicted to be  $1.85 \text{ g/cm}^3$ . The HOF of the compound was predicted as  $808.5 \text{ kJ/mol}$ . The heat of detonation, detonation pressure, and detonation velocity of 5-ATHTO, as predicted by the K-J equation, were  $1504 \text{ J/g}$ ,  $32.6 \text{ GPa}$ , and  $8.25 \text{ km/s}$ , respectively. The 50% drop height during impact sensitivity testing was  $52 \text{ cm}$ , indicating that this is an insensitive energetic compound with good detonation performance.

Sodium 5,5'-bistetrazole-1,1'-diolate tetrahydrate (SBTD•4H<sub>2</sub>O), a key intermediate for the synthesis of energetic salts based on 1,1'-dihydroxyl-5,5'-bistetrazole (BTD), was synthesized by a one-pot synthesis using dichloroglyoxime as starting material. It was characterized by IR, XRD, DSC, TGA, elemental analysis, SEM, and impact and friction sensitivity [981]. SBTD•4H<sub>2</sub>O crystallized in triclinic space group  $P1$  and the cell parameters were  $a = 5.6440(11) \text{ \AA}$ ,  $b = 6.4476(17) \text{ \AA}$ ,  $c = 8.303(11) \text{ \AA}$ ,

$\angle\alpha = 100.131(5)^\circ$ ,  $\angle\beta = 96.789(3)^\circ$ ,  $\angle\gamma = 112.157(3)^\circ$ ,  $V = 1$ , and  $D_c = 1.761 \text{ g/cm}^3$ . At the heating rate of  $10 \text{ K min}^{-1}$ ,  $\text{SBTD} \cdot 4\text{H}_2\text{O}$  started to lose crystal water at  $84.4^\circ\text{C}$ . It began to decompose at  $641.9 \text{ K}$  ( $368.8^\circ\text{C}$ ), with a peak decomposition temperature of  $671.7 \text{ K}$  ( $398.6^\circ\text{C}$ ). This indicated that  $\text{SBTD} \cdot 4\text{H}_2\text{O}$  had good thermal stability. Impact sensitivity  $H_{50}$  of  $\text{SBTD} \cdot 4\text{H}_2\text{O}$  was greater than  $100 \text{ cm}$ .

Dilithium 5,5'-bistetrazole-1,1'-diolate, disodium 5,5'-bistetrazole-1,1'-diolate, and dipotassium 5,5'-bistetrazole-1,1'-diolate were synthesized from 5,5'-bistetrazole-1,1'-diole with high yields of over 90%. Dihydroxylammonium 5,5'-bistetrazole-1,1'-diolate was synthesized by an ion exchange reaction with lithium ions with a high yield of 94% [982]. The enthalpies of dissolution and the entropies of dissolution of these salts were measured.

Studies of the thermal decomposition under non-isothermal and isothermal conditions, enthalpy of formation, burning behavior, and flame structure of dihydroxylammonium 5,5'-bistetrazole-1,1'-diolate ( $\text{C}_2\text{H}_8\text{N}_{10}\text{O}_4$ , TKX-50) have shown that TKX-50 burns slightly faster than HMX and approaches the burning rate of CL-20 [983]. The combustion of TKX-50 has been shown to obey a mechanism, with the leading reaction taking place in the condensed phase. The rates of TKX-50 decomposition in both solid and liquid phases proved to be slightly higher than the corresponding rates of decomposition of RDX. Decomposition of TKX-50 is initiated by the decomposition of free hydroxylamine formed in the reaction of dissociation of the salt. An intermediate decomposition product is the ammonium salt of 5,5'-bis(2-hydroxytetrazole), which then further decomposes in the second stage at elevated temperatures. The energy of combustion in a calorimeter bomb under oxygen pressure was  $\Delta U_{\text{comb}}(\text{TKX-50}) = 8704 \pm 53 \text{ J/g}$  or  $2054 \pm 16 \text{ kJ/mol}$  with a molecular mass of  $\text{TKX-50} = 236.15 \text{ g/mol}$ . From this, one calculates the enthalpy of formation  $\Delta H_f^{298}$  as  $+111 \pm 16 \text{ kJ/mol}$ . This was quite different from the enthalpy of formation reported by other sources ( $+446.6 \text{ kJ/mol}$ ). In the DSC thermograms, a narrow and sharp exothermic peak corresponding to thermal decomposition was visible at  $493\text{--}518 \text{ K}$  ( $220\text{--}245^\circ\text{C}$ ) depending on the heating rate. A second more extended exothermic peak was observed at  $278\text{--}290^\circ\text{C}$ .

The decomposition of TKX-50 in TGA experiments occurred in two stages. The first stage ended after 44% mass had been lost ( $463\text{--}519 \text{ K} = 190\text{--}236^\circ\text{C}$ ). The second, slightly slower stage resulted in about 25% solid residue ( $638 \text{ K} = 365^\circ\text{C}$ ). The kinetic rate equation for the TKX-50 decomposition was

$$k = 5.0 \times 10^{13} \exp(18840/T) \text{ s}^{-1}$$

and the activation energy was  $E_a = 156.6 \text{ kJ/mol}$ . When measuring the strand burning rate of TKX-50 pellets in a windowed combustion bomb, it was found that TKX-50 burned slightly faster than HMX and approached the burning rate of CL-20. The dependence of the burning rate on pressure displayed a break at a pressure of  $5 \text{ MPa}$ . Figure 21 shows a comparison of the burn rate of TKX-50 with that of CL-20 and HMX.

**Figure 21:** Strand burning rate of TKX-50 in comparison to that of CL-20 and HMX. (Reprinted and modified from Sinditskii et al. 2015, with permission from ©2015 Elsevier; permission conveyed through RightsLink.)

The calculated detonation velocity of TKX-50 (9190 m/s at the maximum density of 1.877 g/cm<sup>3</sup>) was slightly less than the detonation velocity of HMX (9230 m/s at the maximum density of 1.904 g/cm<sup>3</sup>) but higher than the velocity of RDX detonation (8990 m/s at the maximum density of 1.806 g/cm<sup>3</sup>).

Dihydroxylammonium 5,5'-bistetrazole-1,1'-diolate is an energetic material with low sensitivity and excellent calculated detonation performance. The compatibility of TKX-50 with nitrocellulose (NC), an NC/NG mixture (mass ratio 1.25:1), TNT, RDX, AP, hexanitroethane, HMX, HNIW (CL-20), GAP, HTPB, aluminum powder, boron powder, and centralite was studied by DSC [984]. The results showed that TKX-50/hexanitroethane possessed good compatibility, TKX-50 and HMX had moderate compatibility, but the compatibility of TKX-50 with TNT, CL-20, centralite, NC, AP, Al, GAP, TKX-50/RDX, TKX-50/NC + NG, TKX-50/B, and TKX-50/HTPB was poor.

Thermal decomposition of dihydroxylammonium 5,5'-bistetrazole-1,1'-diolate (TKX-50) was studied using TGA, DSC, and ARC [985]. Non-isothermal and isothermal kinetic parameters were obtained at both atmospheric and low (up to 0.3 Torr) pressures. The gas products of thermolysis were detected *in-situ* using IR spec-

troscopy and the structure of solid-state decomposition products was determined by XRD and SEM. Diammonium 5,5'-bitetrazole-1,1'-diolate was directly identified to be the most important intermediate of the decomposition process. None of the Arrhenius parameters reported before could properly describe the complex two-stage decomposition process of TKX-50. Nonetheless, isoconversional methods combined with isothermal measurements yielded the most reliable kinetic parameters of TKX-50 thermolysis. In contrast to the literature reports, the thermal stability of TKX-50 was determined in the ARC experiments to be lower than that of RDX but close to that of CL-20.

Hydrazinium 5,5'-bitetrazole-1,1'-diolate (HA • BTO) was prepared by the reaction of 1*H*,1'*H*-5,5'-bitetrazole-1,1'-diolate (BTO) with hydrazinium(1+) chloride and was fully characterized [986]. XRD results showed that the salt belongs to the triclinic space group  $P\bar{1}$  with a relatively high density of 1.912 g/cm<sup>3</sup> at 298 K. The salt had good thermal stability with an onset of decomposition temperature above 473 K (200 °C). The enthalpy of formation based on the heat of combustion measured by oxygen bomb calorimetry was +425.6 kJ/mol, which is the same level as TKX-50 and four times higher than that of RDX. The predicted detonation pressure and detonation velocity of the salt was calculated as 36.1 GPa and 8931 m/s, which are higher than those of RDX. The impact and friction sensitivities were 28 J and 120 N, which are better than those of TKX-50.

Two salts based on 1*H*,1'*H*-5,5'-bitetrazole-1,1'-diolate (BTO) anion with pyrazole (**1**) and imidazole (**2**) cations were synthesized via metathetical reactions [987]. Structural characterization was done by elemental analysis, FTIR, NMR, XRD, and MS. Thermal analysis by DSC and TGA-DTG provided data for the calculation of non-isothermal kinetic parameters. Both salts showed acceptable thermal stabilities as the decomposition temperatures were above 473 K (200 °C). The enthalpies of formation for these salts calculated using the measured heat of combustion were +70.6 kJ/mol for (**1**) and -47.8 kJ/mol for (**2**), respectively.

*Ab initio* calculations for a series of energetic ionic salts based on 5,5'-bitetrazole-1,1'-diolate predicted the physicochemical and detonation characteristics of these energetic ionic salts, including structural, electronic, vibrational, and performance parameters (enthalpies of formation, detonation pressures, and detonation velocities) [988]. Strong intermolecular hydrogen bonds are observed in hydrazinium and hydroxylammonium cations compared to other cations. Hydroxylammonium and hydrazinium cations produce the highest density that is relative to other cations when combined with the 5,5'-bitetrazole-1,1'-diolate anion.

#### 14.9.4.2 1,1'-Dinitramino-5,5'-bitetrazole

1,1'-Dinitramino-5,5'-bitetrazole, *N*-[5-(1-nitramidotetrazol-5-yl)tetrazol-1-yl]nitramide, C<sub>2</sub>H<sub>2</sub>N<sub>12</sub>O<sub>4</sub>, is an energetic material with an acidic character. It forms energetic salts with many bases.

1,1'-Dinitramino-5,5'-bitetrazole

Potassium 1,1'-dinitramino-5,5'-bitetrazolate is one of the most energetic primary explosives. This is due to its high initiation power and the exclusion of heavy metals like lead. The alkali metal salts such as the lithium, sodium, rubidium, and cesium salts were synthesized by reaction of the highly soluble ammonium salt with the corresponding metal hydroxide solutions [989]. In addition, the highly explosive silver salt and several other transition metal(II) amine complexes with nickel, copper, and zinc were prepared in a similar manner. The structure of all compounds was determined by XRD. The sensitivities toward impact, friction, heat, and ESD and their behavior on laser irradiation of the transition metal complexes were explored.

#### 14.9.4.3 Ditetrazolylamine

Instead of linking two tetrazole rings over the C—C bond at the 5-position, they can be linked via a C—NH—C bridge, forming a secondary amine, ditetrazolylamine, also known as imino-bis-tetrazole, bistetrazolylamine, bis-(1(2)*H*-tetrazol-5-yl)-amine, 5,5'-bis(1*H*-tetrazolyl)-amine, H2BTA, BTA, often obtained as *N*-1*H*-tetrazol-5-yl-1*H*-tetrazol-5-amine monohydrate; 2*H*-tetrazol-5-amine, *N*-2*H*-tetrazol-5-yl-, hydrate (1:1); C<sub>2</sub>H<sub>3</sub>N<sub>9</sub>•H<sub>2</sub>O, CAS RN [251110-84-6], *M* = 171.12 (hydrate). This compound has a melting point of 536 K (263 °C) (decomp.) This compound may also confusingly be called imino-5,5'-bistetrazole or *N,N*-bis(1*H*-tetrazol-5-yl)amine or 5-(tetrazol-5-ylamino)tetrazole. A more correct name would be di-5,5'-tetrazolylamine or ditetrazol-5-yl-amine [841, 990]. It usually is obtained in the form of a monohydrate which is also called BTA $\mathbf{w}$  (the  $\mathbf{w}$  stands for *water*).

Linking two tetrazole rings at the 5-position via an —NH— group gives ditetrazol-5-ylamine (imino-5,5'-bistetrazole). It can give off two protons and form dibasic salts with strong bases. A bis(4-aminotriazolium) imino-5,5'-bistetrazolate would be a compound with a record high nitrogen content (C<sub>6</sub>H<sub>4</sub>N<sub>17</sub> = 75.8 mass-% nitrogen).

Di(tetrazol-5-yl)amine has been synthesized in a four-step process starting with cyanuric chloride. It is characterized by IR spectroscopy and <sup>1</sup>H and <sup>13</sup>C NMR [991].

The kinetic and activation parameters of the decomposition in air and argon have been determined over the temperature range of 473–515 K (200–242 °C). The kinetic curves had an evident S-shape and fitted an equation of autocatalysis of the first order

$$\frac{d\alpha}{dt} = k_1(1 - \alpha) + k_2\alpha(1 - \alpha),$$

where the rate constant of non-catalytic decomposition  $k_1$  and the rate constant of catalytic reaction  $k_2$  satisfy the Arrhenius equations

$$k_1 = 10^{15.6 \pm 0.5} \exp[-(197 \pm 5)/RT] \text{ s}^{-1}$$

and

$$k_2 = 10^{17.5 \pm 0.7} \exp[-(201 \pm 7)/RT] \text{ s}^{-1}$$

( $R$  is measured in  $\text{kJ mol}^{-1} \text{ K}^{-1}$ ). Every 5,5'-bis(tetrazolyl)amine molecule splits out 2.5 molecules of  $\text{N}_2$ . The purity of nitrogen formed is better than 97.5 vol.-%. The evolution of  $\text{N}_2$  is accompanied by the formation of the condensed product of an unusual structure. The calorimetric data have confirmed the autocatalytic manner of the decomposition. The total reaction heat is about 440 cal/g.

The acid-catalyzed cyclization reaction of sodium dicyanamide and sodium azide in the ratio of 1:2 produced 5,5'-bis(1*H*-tetrazolyl)amine (also called di-1*H*-tetrazol-5-yl amine) in high yield (88%) as the monohydrate [992]. Dehydration of the monohydrate at an elevated temperature and reduced pressure gave anhydrous 5,5'-bis(1*H*-tetrazolyl)amine, which exhibited greater impact sensitivity than the hydrated form, BTaw. A BTaw sample with no excess water was obtained by drying at 323 K (50 °C), whereas anhydrous BTA was generated by removing water of hydration at 393 K (120 °C). The HOF of BTaw is +203 kJ/mol, while the HOF of anhydrous BTA is +633 kJ/mol, derived from measured heats of combustion of 1714 and 1858 kJ/mol, respectively. Predicted detonation velocities were 7792 m/s for BTaw and 9120 m/s for BTA. Predicted detonation pressures were 220 kbar for BTaw and 343 kbar for BTA, as calculated using the program EXPLO5. Di-1*H*-tetrazol-5-yl amine forms complexes with copper salts [993].

Thermoanalytical experiments were performed on bis-(1(2)*H*-tetrazol-5-yl)-amine monohydrate and anhydrous bis-(1(2)*H*-tetrazol-5-yl)-amine in an effort to better characterize the thermal stability and decomposition of these compounds by doing ARC, DSC, and TGA heating rate studies in a helium atmosphere [994, 995]. A two-step mass loss was observed in all experiments. The first step represents dehydration and the second step is a result of decomposition. An initial 9–10% mass loss was observed in the 403–433 K (130–160 °C) range. This corresponded to the loss of 1 mol of  $\text{H}_2\text{O}$  from 1 mol of BTaw. The average enthalpy of dehydration was  $268 \pm 15 \text{ J/g}$  or  $43 \pm 2 \text{ kJ/mol}$  BTaw. Kinetic parameters were determined for both of these steps using several different methods. The activation energy of BTaw (BTA) decomposition was  $193 \pm 5 \text{ kJ/mol}$ .

EGA was used to determine the composition of gaseous decomposition products. Hydrogen azide, ammonia, and hydrogen cyanide appeared as the major products in the FTIR trace, beginning at approximately 513 K (240 °C).

High-energy density salts that contained nitrogen-rich cations and the 5-(tetrazol-5-ylamino)tetrazolate anion were synthesized by metathesis reactions of sulfate salts with barium compounds such as bis[5-(tetrazol-5-ylamino)tetrazolate] or barium iminobis(5-tetrazolate) in an aqueous solution. They were characterized by IR, NMR spectroscopy, elemental analysis, DSC, and impact sensitivity [952].

5,5'-Bis(1*H*-tetrazolyl)amine. 5,5'-bis(1*H*-tetrazolyl)amine (BTA) was investigated under compression at room temperature [996]. Powder XRD using synchrotron radiation and micro-Raman spectroscopy were carried out to pressures up to 12.9 GPa. BTA conserved the crystalline structure of its room condition phase up to the highest pressure, i.e., an orthorhombic unit cell (*Pbca*).

#### 14.9.4.4 4,5-Di(tetrazol-5-yl)-1,2,3-triazole

Instead of linking two tetrazole rings directly over the C—C bond at the 5-position, they can also be linked via a triazole ring as a go-between. The resulting molecule has three azole rings linked by C—C bonds. 5,5'-(1*H*-1,2,3-Triazole-4,5-diyl)bis-1*H*-tetrazole, also known as 4,5-di(tetrazol-5-yl)-1,2,3-triazole; 2*H*-tetrazole, 5-[4-(2*H*-tetrazol-5-yl)-1*H*-1,2,3-triazol-5-yl]-; 5-[4-(1*H*-tetrazol-5-yl)-1*H*-triazol-5-yl]-1*H*-tetrazole, ditetrazolyltriazole, LLM-137, CAS RN [869060-66-2], C<sub>4</sub>H<sub>3</sub>N<sub>11</sub>, *M* = 205.15 g/mol, has a predicted density of 2.035 g/cm<sup>3</sup>.

4,5-Di(tetrazol-5-yl)-1,2,3-triazole

4,5-Bis(tetrazol-5-yl)-1,2,3-triazole can be made by dissolving ZnCl<sub>2</sub>, NaN<sub>3</sub>, and 4,5-dicyano-1,2,3-triazole in an organic solvent, refluxing for 0.5–2 h, filtering, collecting the precipitated solid, adding it to a basic solution, stirring, filtering, collecting the filtrate, regulating pH to 1, vacuum filtration, washing, and drying [256].

#### 14.9.4.5 Other Ditetrazole Derivatives

DFT computations were performed to study the effects of different substituents and bridge groups on the enthalpies of formation, thermal stability, and predicted detonation properties for a series of diiminotetrazole derivatives [997]. The isodesmic reac-

tion method was used to calculate the enthalpies of formation of the derivatives using total energies obtained from electronic structure calculations. The BDE and bond orders for the weakest bonds were analyzed to see what limits the thermal stability of the diiminotetrazole derivatives. The detonation velocities and pressures were predicted by the semi-empirical K-J equations and were based on the theoretical densities and enthalpies of formation.

#### 14.10 Azotetrazole, Azoxytetrazole, Hydrazotetrazole, and Azotetrazolates

Azotetrazoles are sometimes called azobistetrazoles or azoditetrazoles, however, the “bis” or “di” specifier is unnecessary. The correct name, as per the Chemical Abstracts and IUPAC guidelines, is 5,5'-(1,2-diazenediyl)bis[2*H*-tetrazole], or bis(1*H*-tetrazol-5-yl)diazene, C<sub>2</sub>H<sub>2</sub>N<sub>10</sub>, CAS RN [28623-02-1].

Symmetrical azotetrazoles can connect the —N=N— bridge to the tetrazole rings either at the carbon atoms at the 5-positions or at the nitrogen atoms such as the nitrogen atoms in the 1-positions of the tetrazole ring. If the connection is to the nitrogen atoms in the 1-positions, a continuous chain of ten nitrogen atoms is formed and the compound is called 1,1'-azotetrazole or 1,1'-(1,2-diazenediyl)bis1*H*-tetrazole, CAS RN [1282522-34-2] or “N10.” The 5,5'-azotetrazole is the more common form because 5-AT as a starting reactant is more readily available than 1-AT.

Azotetrazole can be made by oxidizing aminotetrazole in an alcoholic solution with permanganates or peroxydisulfates [998]. Azotetrazole in free form at room temperature is unstable. In water, it quickly converts into hydrazinotetrazole, which is accompanied by the release of nitrogen.

The reaction of 1-aminotetrazole with acidic sodium dichloroisocyanurate produced 1,1'-azo(tetrazole) [999]. The unusual chain of ten nitrogen atoms in this compound was confirmed by XRD. The physical and explosive properties of the azo compound were characterized.

The detailed potential energy surface of N10 was investigated using quantum mechanical calculations. Probable decomposition pathways were outlined by canonical transition state theory modeling [1000]. Among all the channels of reactions studied, ring-opening of the N<sub>10</sub> compound, followed by N<sub>2</sub> elimination to form a linear molecule was predicted to be the primary decomposition channel. Based on the thermal decomposition mechanism of N10, the probability of being successful in attempting to synthesize N12 and N14 was explored. These longer nitrogen chain compounds having higher nitrogen content than N10 would make good HEDMs. By comparing their energetic barriers with the corresponding primary N<sub>2</sub>-elimination reaction of N10, it was concluded that the predicted structures could theoretically exist at room temperature.

As a first step in this direction, a stable catenated N11 salt was synthesized by an azo coupling reaction from 1,5-diaminotetrazole [1001]. This was the first example of an azo reaction between an N—NH<sub>2</sub> diazonium salt and an amine derivative. The product structure was confirmed by XRD and its physical and explosive properties were characterized.

Unfortunately, 5,5'-azotetrazolates are not stable under mineral-acidic conditions because neutral 5,5'-azotetrazole decomposes into 5-hydrazinotetrazole, dinitrogen, and formic acid. With dilute nitric acid, the degradation produced 5-azidotetrazole as well as gaseous products [1002]. An effort has been started to replace 5,5'-azotetrazolates with bitetrazolates. The corresponding salts of 5,5'-bitetrazole are stable in acidic media and show performance similar to 5,5'-azotetrazolates.

Ammonium, guanidinium, or triaminoguanidinium azotetrazolates were synthesized, characterized, and thermolyzed [1003, 1004].

Guanidinium azotetrazolate was thermally the most stable of the three salts and had the highest heat release (2804 J/g) during its exothermic decomposition (Table 62). FTIR of the decomposition products of azotetrazolate salts showed bands at 3264 and  $2358\text{ cm}^{-1}$  which may be attributed to gaseous species such as  $\text{NH}_3$  and  $\text{HCN}$  or  $\text{NH}_2\text{CN}$ . The sensitivity test results showed that ammonium azotetrazolate (AZT) and guanidinium azotetrazolate are insensitive to impact and friction stimuli ( $\text{H50\%} > 170\text{ cm}$  and  $> 36\text{ kg}$ ) while TAGAZ (sometimes also designated as TAGzT) exhibited a relatively sensitive nature (drop weight  $\text{H50\%}$  51 cm and friction load  $157\text{ N} = 16\text{ kg}_f$ ). Triaminoguanidinium azotetrazolate (abbreviated as TAGAZ or TAGzT) was incorporated into solid propellant formulations to establish the compatibility of this class of compounds. The burning rate data obtained indicated that triaminoguanidinium azotetrazolate acted as an efficient energetic additive in CMDDB propellant formulations in the high-pressure region.

**Table 62:** Thermal stability of azotetrazolate salts (DSC results).

|       | Onset temperature of decomposition, $T_i$ |     | Maximum of exotherm, $T_{max}$ |     | Final temperature of exotherm, $T_f$ |     | Heat release during decomposition |
|-------|-------------------------------------------|-----|--------------------------------|-----|--------------------------------------|-----|-----------------------------------|
|       | °C                                        | K   | °C                             | K   | °C                                   | K   | J/g                               |
| AAZ   | 181                                       | 454 | 212                            | 485 | 226                                  | 499 | 1380                              |
| GAZ   | 182                                       | 455 | 259                            | 532 | 261                                  | 534 | 2804                              |
| TAGAZ | 181                                       | 454 | 204                            | 477 | 221                                  | 494 | 1352                              |

Data source: [1004].

The synthesis, characterization, and thermolysis studies of hydrazinium azotetrazolate (HAZ) by TGA and DSC indicated that hydrazinium azotetrazolate decomposed in the range of 423–453 K (150–180 °C) [1005]. The pattern of decomposition of HAZ dihydrate was predicted with the help of the pyrolysis GC/MS technique and a probable decomposition mechanism was proposed.

DFT methods were used to study the enthalpies of formation ( $\Delta H_f$ 's), electronic structure, energetic properties, and thermal stability for bridged bitetrazole (ditetrazole) derivatives with different linkages between the rings and different substituent groups on the rings [1006]. The  $-N_3$  group and azo bridge ( $-N=N-$ ) are effective in increasing the  $\Delta H_f$ 's of the bitetrazole derivatives. The calculated detonation velocities and detonation pressures indicated that the  $-NO_2$ ,  $-NF_2$ ,  $-N=N-$ , or  $-N(O)=N-$  group are effective for enhancing the detonation performance for these compounds. An analysis of the BDE for several relatively weak bonds suggested that the N–N bond in the rings or outside the rings is the weakest one and N–N cleavage is likely to happen first in thermal decomposition. Overall, the  $-CH_2-CH_2-$  or  $-NH-NH-$  group is an effective bridge for enhancing the thermal stability of the bridged bitetrazoles. The enthalpy of formation of 5,5'-hydrazotetrazole,  $C_2H_4N_{10}$ ,  $M = 168.12$  g/mol, is  $+804$  cal/g =  $+135$  kcal/mol =  $+565$  kJ/mol. It contains 83.3% nitrogen. Other azotetrazolate salts are described in [972] and [1007].

A two-step synthesis method for some azotetrazolate non-metallic salts was introduced, including for guanidinium, aminoguanidinium, diaminoguanidinium, and triaminoguanidinium azotetrazolate [1008]. The physical and chemical properties and explosive performance of the ammonium salt and hydrazinium salt were also studied. It was shown that these materials have high HOF, large gas production, good thermal stability, and high heat of reaction, and they may have possible applications as gas generants, low-signature propellants, low-smoke, or non-smoke pyrotechnics, and high-performance explosives.

DFT methods with corrections for long-range dispersion interactions were evaluated for their capabilities to describe the crystallographic lattice properties of a set of

26 high nitrogen-content salts including eight azotetrazolates and five iminobistetrazolates [1009].

DFT calculations were used to study two compounds, 1,1'-azobis(tetrazole) and 1,1'-azobis(5-methyltetrazole), with a ten-catenated nitrogen atoms chain [1010]. In addition to this, the structures of substituted azobis(tetrazoles) with ten catenated nitrogen atoms and various energetic groups ( $-\text{CF}_3$ ,  $-\text{C}(\text{NO}_2)_3$ ,  $-\text{N}_3$ ,  $-\text{NH}_2$ ,  $-\text{NHNH}_2$ ,  $-\text{NHNO}_2$ ,  $-\text{NO}_2$ ,  $-\text{OCH}_3$ ,  $-\text{OH}$ , and  $-\text{ONO}_2$ ) were computed. The optimized geometry, frontier MOs, electrostatic potential, and IR and NMR spectra were calculated. The effects of different substituents on the density, enthalpy of formation, heat of explosion, detonation velocity, and pressure and sensitivity of the azobis(tetrazole) derivatives were then examined. The properties of several compounds were predicted to be superior to CL-20, RDX, or HMX.

A similar family of salts was derived from azotetrazole, which carries a hydroxyl group on each of the two tetrazole rings, 5,5'-azotetrazole-1,1'-diol. The following sections provide information on specific azotetrazolate salts.

#### 14.10.1 Alkali Metal 5,5'-Azotetrazolates

5,5'-Azotetrazolate salts have been known for more than 120 years and a lot of work was done on these compounds since they were first discovered. 5,5'-Azotetrazole is a dibasic acid and can form salts in which one or both rings carry a negative charge. Salts of azotetrazole were prepared in 1898 by Thiele by oxidation of 5-AT with potassium permanganate. The same process is still in use today. Azotetrazolates, of a heavy metal, were later patented as primary explosives in initiators and blasting caps because they are stab-sensitive. The lead salt may be even more drop-weight sensitive than mercury fulminate. The alkali metal and earth alkaline metal salts of 5,5'-azotetrazole are well characterized. Na, K, Ca, Ba, and  $\text{NH}_4$  salts of azotetrazole were the first ones to be discovered and have their properties described. They crystallize with two to eight molecules of water in the sphere of hydration. Loss of water increases their friction and shock sensitivity remarkably. Sodium 5,5'-azotetrazolate can be obtained by oxidation of 5-AT with sodium permanganate. It is often used as an intermediate in the preparation of other azotetrazolate salts that are even more rich in nitrogen. Five water molecules are complexed to the azotetrazolate ion. 5-aminotetrazole (5-AT) is added to a 2-M aqueous solution of sodium hydroxide, followed by the addition of potassium permanganate, which produces the NaZT. The insoluble  $\text{MnO}_2$  byproduct forms a sludge that is difficult to filter while the solution is still hot.

5,5'-Azotetrazole synthesis

Replacing the alkaline metal with nitrogen-rich cations such as ammonium, hydrazinium, guanidinium, or triaminoguanidinium leads to the synthesis of stable high-nitrogen compounds. These have received a lot of attention since the search began for safer automotive airbag inflator gas generants [1011–1013].

Alkaline earth metal salts of 5,5'-hydrazine-1,2-diylbis(1*H*-tetrazole) can be used as flame colorants in pyrotechnic flares and display fireworks, thus eliminating the need for environmentally unfriendly perchlorates or chlorates [1014].

#### 14.10.2 Ammonium 5,5'-Azotetrazolate

The enthalpy of formation of ammonium 5,5'-azotetrazolate is +443 kJ/mol (+105.9 kcal/mol).

#### 14.10.3 Hydrazinium(1+) 5,5'-Azotetrazolate

The enthalpy of formation of hydrazinium(1+) 5,5'-azotetrazolate is +858 kJ/mol [61]. The reaction of  $[\text{N}_2\text{H}_5^+]_2[\text{SO}_4]^{2-}$  with barium 5,5'-azotetrazolate gave new HEDMs based on the 5,5'-azotetrazolate dianion [901, 1015]. The dihydrazinium salt of  $[\text{N}_4\text{C}-\text{N}=\text{N}-\text{CN}_4]^{2-}$  (**1**), its dihydrate (**2**), and its dihydrazinate (**3**) were prepared and characterized. Synthesis in water produced yellow needles of the dihydrate  $[\text{N}_2\text{H}_5^+]_2[\text{N}_4\text{C}-\text{N}=\text{N}-\text{CN}_4]^{2-} \cdot 2\text{H}_2\text{O}$  (**2**): monoclinic,  $P2_1/c$ ,  $a = 8.958(2) \text{ \AA}$ ,  $b = 3.6596(7) \text{ \AA}$ ,  $c = 16.200(3) \text{ \AA}$ ,  $\beta = 96.834(3)^\circ$ ,  $V = 527.3(2) \text{ \AA}^3$ ,  $Z = 2$ , and  $\rho_{\text{X-ray}} = 1.564 \text{ g/cm}^3$ . Synthesis in anhydrous hydrazine instead of water gave yellow dihydrazinate crystals  $[\text{N}_2\text{H}_5^+]_2[\text{N}_4\text{C}-\text{N}=\text{N}-\text{CN}_4]^{2-} \cdot 2\text{N}_2\text{H}_4$  (**3**): triclinic,  $P\bar{1}$ ,  $a = 4.6208(6) \text{ \AA}$ ,  $b = 8.585(1) \text{ \AA}$ ,  $c = 9.271(1) \text{ \AA}$ ,  $\alpha = 108.486(2)^\circ$ ,  $\beta = 95.290(2)^\circ$ ,  $\gamma = 102.991(2)^\circ$ ,  $V = 334.51(8) \text{ \AA}^3$ ,  $Z = 1$ , and  $\rho_{\text{X-ray}} = 1.461 \text{ g/cm}^3$ . The compounds were characterized by elemental analysis and vibrational (IR, Raman) and multi-nuclear NMR spectroscopy ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ,  $^{15}\text{N}$ ). These compounds represent high nitrogen HEDMs with one of the highest nitrogen contents reported to date:

- (1)  $[\text{N}_2\text{H}_5^+]_2[\text{N}_4\text{C}-\text{N}=\text{N}-\text{CN}_4]^{2-} = \text{C}_2\text{H}_{10}\text{N}_{14} = 85.2\%$
- (2)  $[\text{N}_2\text{H}_5^+]_2[\text{N}_4\text{C}-\text{N}=\text{N}-\text{CN}_4]^{2-} \cdot 2\text{H}_2\text{O} = \text{C}_2\text{H}_{14}\text{N}_{14}\text{O}_2 = 73.3\%$
- (3)  $[\text{N}_2\text{H}_5^+]_2[\text{N}_4\text{C}-\text{N}=\text{N}-\text{CN}_4]^{2-} \cdot 2\text{N}_2\text{H}_4 = \text{C}_2\text{H}_{18}\text{N}_{18} = 85.7\%$ .

The standard HOF of the solvate-free compound (**1**) was computed to be  $\Delta H_f^\circ = 264 \text{ kcal/mol} = 1147 \text{ kcal/kg} = 1105 \text{ kJ/mol}$  and is one of the highest ever reported. The compounds are stable at room temperature and are almost insensitive to friction and impact, however, they detonate violently when the explosion is initiated, e.g., by rapid heating over the decomposition temperature or by using an initiator. No detonation was observed in the drophammer test (5 kg, 50 cm). In the DTA/TGA measurements at a heating rate of 5 K/min, and using samples of about 12 mg in open aluminum crucibles, the first mass loss after the evaporation of water in (**2**) and hydrazine in (**3**) was detected at about 393 K (120 °C) followed by explosion at 436 K = 163 °C and 447 K = 174 °C.

Similar salts were obtained from dimethylamine, trimethylhydrazine, and 5,5'-azotetrazole [1016]. Ammonium and hydrazinium salts of the 5,5'-azotetrazolate dianion with methylated ammonium and hydrazinium cations were prepared. The compounds were characterized by elemental analysis, vibrational (IR, Raman) spectroscopy, and multi-nuclear ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ) NMR spectroscopy. The crystal structures of the di[ammonium], the bis[dimethylammonium], and the bis[trimethylhydrazinium] 5,5'-azotetrazolate salts were determined. Additional 5,5'-azotetrazolate salts of alkylhydrazines, guanidine, and triaminoguanidine were prepared and characterized by elemental analysis, vibrational (IR, Raman) spectroscopy, and multi-nuclear ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ) NMR spectroscopy [1017]. The crystal structures of the di-tert-butylhydrazinium, the ethylenedihydrazinium, the diguanidinium, and the bis-triaminoguanidinium azotetrazolate were determined. The thermal, shock, and friction sensitivities of all compounds were investigated and their explosion products were analyzed.

The thermal decomposition of hydrazinium azotetrazolate was evaluated in comparison to GuN, TAGN, and TAGAT and five other nitrogen-rich additives [1018]. In contrast to similar guanidinium or triaminoguanidinium salts, hydrazinium azotetrazolate was found to decompose in a single stage (Figure 22).

The steep slope in the TGA thermogram corresponded to the exothermic decomposition observed in the simultaneous DTA between 396 and 441 K (123 and 168 °C), resulting in a substantial 77% weight loss followed by an endothermic decomposition resulting from the breakage of relatively strong C–N bonds in the residue. This suggests that the decomposition initiated with the homolytic cleavage of N–NH<sub>2</sub> bonds and was followed by the exothermic opening of the azotetrazolate ring.

The structure of dihydrazinium 5,5'-azotetrazolate dihydrate was determined by neutron diffraction at 25 K and revealed no significant deviations from the previously reported room-temperature structure determined by XRD [1019]. The vibrational spectrum of dihydrazinium 5,5'-azotetrazolate dihydrate was also measured at 25 K by inelastic neutron scattering (INS) spectroscopy. Solid-state quantum chemical calculations were used to simulate the INS spectrum. Based on the simulations and analysis of the experimental data, it was possible to assign the normal vibrational modes. This helped to explain the decomposition mechanism of this compound.

**Figure 22:** DTA-TGA thermogram of hydrazinium azotetrazolate. (Republished and modified from [1018], with permission of the ©2009 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

The isothermal structural properties, equation of state, and vibrational dynamics of dihydrazinium 5,5'-azotetrazolate dihydrate were studied under high pressure using synchrotron XRD and optical Raman and IR micro-spectroscopy [1020]. At pressures near 4.5 GPa, XRD characterization revealed an abrupt discontinuity in the compressibility. When correlated with the mode splitting and intensity changes observed in the spectroscopic measurements, this suggested the onset of a subtle isostructural phase transition.

The enthalpies of formation of a series of salts of 5,5'-azotetrazole with nitrogenous onium bases were determined by calorimetric measurements in a bomb calorimeter with a modified oxygen bomb [1021]. Samples were burnt without using a crucible. The enthalpies of formation were calculated from measured heats of combustion.

The thermal decomposition of guanidinium, ammonium, melaminium, and sodium 5,5'-azotetrazole salts, the kinetic parameters of the controlling chemical reaction, and the detailed decomposition mechanisms of 5,5'-azotetrazole salts have been investigated [1022].

The thermal decomposition of dihydrazinium 5,5'-azotetrazolate under isothermal and non-isothermal conditions in solid and liquid phases was measured and

a relationship between the basicity and the thermal stability of 5,5'-azotetrazole salts was demonstrated [1023]. A boundary of the possible existence of 5,5'-azotetrazole salts in terms of the basicity index  $pK_a$  was determined. Gaseous and condensed products of decomposition were analyzed and a mechanism of thermal decomposition of 5,5'-azotetrazole was proposed. The enthalpies of formation of some 5,5'-azotetrazole salts were determined and the most reliable values were chosen based on the analysis of the data obtained and those available in publications. The enthalpy of formation of dihydrazinium 5,5'-azotetrazolate is  $+858 \text{ kJ/mol} = +205 \text{ kcal/mol}$ .

#### 14.10.4 Bis(guanidinium) 5,5'-Azotetrazolate

##### 14.10.4.1 Preparation of Bis(guanidinium) 5,5'-Azotetrazolate

Some of the guanidinium salts of nitrogen-rich heterocyclic acids have already been described in *Encyclopedia of Liquid Fuels* in the chapter titled "Amides and Imides." This section describes a few more guanidinium salts that are outstanding because of their good thermal stability and high nitrogen content. Guanidinium 5,5'-azotetrazolate, also known as  $\text{C}_4\text{H}_{12}\text{N}_{16}$ , bis(guanidinium) 5,5'-azotetrazolate, di(guanidinium) 5,5'-azotetrazolate, GZT, GAZ, GuZT, Gu2AzT, can be obtained by reacting 5-aminotetrazole monohydrate with potassium permanganate in an aqueous sodium hydroxide solution to form sodium 5,5'-azotetrazolate dihydrate as an intermediate, then reacting 5,5'-azotetrazolate dihydrate with guanidinium nitrate or guanidinium chloride to obtain guanidinium 5,5'-azotetrazolate [1024–1026]. Properties of this salt are also listed in *Encyclopedia of Liquid Fuels*, in the "Amides and Imides" chapter under guanidinium salts (there may be some duplication of information).

Guanidinium 5,5'-azotetrazolate GAZ GuZT

Guanidinium azotetrazolate (GuZT) was evaluated as an additive for a high regression rate fuel mixture with HTPB [1027]. GuZT was found to react with N100, a common curative for HTPB. A test grain made with N100, HTPB, and GAT formed a foam that was about one and a half times its original volume. An alternative isocyanate curative was found, polyisocyanate (PAPI), with which it did not react.

Guanidinium azotetrazolate can be synthesized from 5-aminotetrazole (5-AT) by oxidation-reduction reactions [1028]. A study of the effects of reaction temperature, reaction time, the molar ratio of reactants, and NaOH concentration on the yield showed that the optimum conditions were as follows: based on 0.1 mol of 5-AT, NaOH concen-

tration was 1.5 mol/L, mol ratio (5-AT):(KMnO<sub>4</sub>) = 3:3, the reaction temperature was 80 °C, and the reaction time was 60 min. Under the optimum conditions, the yield of a scaled-up test was better than 80%. The structure and thermal stability of the compound were characterized by elemental analysis, IR, <sup>1</sup>H-NMR, and TG-DTA.

In previous years, the Naval Surface Warfare Center's Indian Head Division (NSWC-IHD) had made approximately 12 kg of GuZT at the 50-gallon scale. To develop a more efficient process, the engineers more than doubled the quantity of GuZT obtained per batch by increasing the concentration of reactants in the reaction solution [1029]. This was done based on a design of experiments (DOE), screening guanidinium azotetrazolate synthesis parameters for effects on product yield, purity, and particle characteristics for the synthesis of GuZT at the 100-gallon scale. Based on this DOE, by using 20% excess and a more concentrated (1.3 g/mL) solution of guanidinium chloride (Gu-HCl) and cooling to 5 °C before filtering the product maximized the yield. The product had a density of 1.538 g/cm<sup>3</sup>. The product GuZT should be washed with water to remove sodium and chloride ion impurities. Washing with water will cause loss of some of the wanted products. The solubility of GuZT in water at different temperatures is listed in Table 63.

**Table 63:** Solubility of guanidinium azotetrazolate in water.

| Temperature |      | GuZT solubility |
|-------------|------|-----------------|
| K           | °C   | mg/mL           |
| 278         | 5    | 4.4             |
| 305.6       | 32.5 | 6.3             |
| 333         | 60   | 10.4            |

Data source: [1029].

Guanidinium azotetrazolate was synthesized by oxidation and cation replacement with 5-aminotetrazole (5-AT) as the starting material [1030]. Guanidinium azotetrazolate was characterized by FTIR, <sup>1</sup>H NMR, <sup>13</sup>C NMR, elemental analysis, HPLC, MS, and SEM. Thermochemical properties of GuZT were analyzed by DSC and its friction sensitivity and impact sensitivity were tested. The optimal conditions for the synthesis of GuZT were as follows: KOH concentration 1.5 mol/L, *n*(5-AT) : *n*(KMnO<sub>4</sub>) : *n*(GuN) = 1.0:1.0:1.1, oxidation reaction temperature 333 K (60 °C), oxidation reaction time 60 min, cation replacement reaction temperature 353 K (80 °C). Under optimal conditions, the GuZT yield can reach 97% and the purity is higher than 99%. The product crystallized in uniform yellow acicular crystals. The thermal decomposition temperature of GuZT was 529.7 K (256.6 °C).

#### 14.10.4.2 Physical Properties of Bis(guanidinium) 5,5'-Azotetrazolate

The measured enthalpy of formation of bis(guanidinium) 5,5'-azotetrazolate is +410 kJ/mol (+98 kcal/mol) and the calculated enthalpy of formation is +486.5 kJ/mol (+116 kcal/mol). Its melting point is 535 K = 262 °C and its density is 1.54 g/cm<sup>3</sup>. The physical properties of bis(guanidinium) 5,5'-azotetrazolate and related high-nitrogen compounds are summarized in Table 64.

**Table 64:** Physical properties of guanidinium and triaminoguanidinium 5,5'-azotetrazolates.

| Compound name                                 | Gross formula                                  | Mol. mass | Nitro-gen content | Den-sity  | Melting point |            | Enthalpy of formation | Refer-ences  |
|-----------------------------------------------|------------------------------------------------|-----------|-------------------|-----------|---------------|------------|-----------------------|--------------|

#### 14.10.4.3 Thermal Stability of Bis(guanidinium) 5,5'-Azotetrazolate

GuZT is thermally quite stable and suffers a weight loss of only 1% after being stored for 50 d at 403 K (130 °C). It melts at a relatively high temperature of 511–512 K (238–239 °C). A comparative thermal stability evaluation of GuZT in comparison to several other azotetrazolate salts showed that GuZT was the thermally most stable compound of the group [1031].

Bis(guanidinium) 5,5'-azotetrazolate thermal decomposition studies were carried out using DSC with 2–3 mg samples pressed in aluminum caps and heated at different rates [1034, 1035]. When heated at a rate of 10 K/min, GuZT has only one exothermic peak at 535 K = 262 °C with an energy release of 837–1255 J/g (200–300 cal/g). Plotting the decomposition rate vs. 1/*T* gives a rather high activation energy of 194 kJ/mol (46.3 kcal/mol). Manometric experiments were carried out in thin-walled glass manometers of the compensation type (glass Bourdon gauge). A sample of GuZT (10–15 mg) was loaded into a vial of 12–15 cm<sup>3</sup> volume. The vial was evacuated,

sealed, and immersed in a thermostat bath containing molten Wood's metal. The temperature in the thermostat was maintained constant with an accuracy of  $\pm 0.5^\circ\text{C}$ . These studies showed that the GuZT is quite thermally stable. The initial rate of GuZT decomposition in the solid state was 10–16 times less than in the melt, while the activation energies were similar (177 and 174 kJ/mol = 42.3 and 41.6 kcal/mol, respectively). GuZT decomposition resulted in the liberation of 3 mols of nitrogen, 1.9 mols of ammonia, and 1 mol of readily condensable products along with the formation of a condensed residue.

The thermal decomposition of bis(guanidinium) 5,5'-azotetrazolate under isothermal and non-isothermal conditions in solid and liquid phases was measured and a relationship between the basicity and the thermal stability of 5,5'-azotetrazole salts was demonstrated [1023]. A boundary of possible existence of 5,5'-azotetrazole salts in terms of the basicity index  $\text{p}K_{\text{a}}$  was determined. Gaseous and condensed products of decomposition were analyzed and a mechanism of thermal decomposition of 5,5'-azotetrazole was proposed. The enthalpies of formation of some 5,5'-azotetrazole salts were determined. The most reliable values were chosen based on the analysis of the data obtained and those available in publications. The enthalpy of formation was +410 kJ/mol (+98 kcal/mol).

#### 14.10.4.4 Burning Rate Studies of Bis(guanidinium) 5,5'-Azotetrazolate

The burning rates of GuZT were measured in the pressure interval 0.1–20 MPa in a constant-pressure bomb of 1.5 L volume that was equipped with windows [1034, 1035]. Samples for testing were prepared as pressed cylinders at 0.82–0.84% of their theoretical maximum density ( $1.538\text{ g/cm}^3$ ) and were confined in transparent acrylic tubes of 4 mm i.d. A video camera was used to determine the character of the combustion process as well as the burning rates. GuZT in the form of samples pressed into 4-mm acrylic tubes can sustain burning at pressures down to 0.2 MPa and showed stable burning above 0.6 MPa. The burning was flameless at all pressures studied and accompanied by the formation of copious white smoke and a solid residue inside the tubes. The burning rate of GuZT at 10 MPa was 25.6 mm/s, which is 1.5 times faster than HMX (Figure 23). The GuZT burning rate-pressure dependence can be expressed as  $r_b = 0.69p^{0.78}$ , mm/s for the pressure interval 0.2–20 MPa.

#### 14.10.4.5 Sensitivity of Bis(guanidinium) 5,5'-Azotetrazolate

The shock and friction sensitivity of bis(guanidinium) 5,5'-azotetrazolate is much less than that of TAGZT or AGZT (Table 65).

#### 14.10.4.6 Applications of Bis(guanidinium) 5,5'-Azotetrazolate

TAGZT and GuZT are being investigated as additives for propellant formulations, not only for the purposes of burning rate modification but also as ingredients that may help existing and future formulations meet the demands of insensitive munitions (IM), safety, and long-term aging requirements. From a performance perspective, TAGZT

**Figure 23:** Strand burning rate of GuZT in comparison to HMX. (Reproduced and modified from [1034] in accordance with Creative Commons CC BY-NC-ND 3.0.)

**Table 65:** Shock and friction sensitivity of GuZT in comparison to TAGZT or AGZT.

| Compound abbreviation | Impact sensitivity |                   | Friction sensitivity |                 |
|-----------------------|--------------------|-------------------|----------------------|-----------------|
|                       | N m                | kg <sub>f</sub> m | N                    | kg <sub>f</sub> |
| TAGZT                 | 1.47–1.57          | 0.15–0.16         | 106                  | 10.8            |
| AGZT                  | 6.9                | 0.7               | 353                  | 36              |
| GuZT                  | 7.4                | 0.75              | 353                  | 36              |

Data source: [1025].

has proven significantly better at increasing the burning rate of RDX-based composite propellants than its similarly structured counterpart, GuZT. Previous thermal decomposition studies have shown that the hydrazine that is formed in the decomposition of TAGzT undergoes a very strong and rapid interaction with RDX. At temperatures near the melting point of RDX, the reaction rate of hydrazine with RDX is faster than the rate of decomposition of RDX by itself. To determine why GUzT is less effective as a burning rate modifier in RDX-based composite propellants, STMBMS and Fourier Transform ion cyclotron resonance (FTICR) mass spectrometry methods were used to

examine the thermal decomposition of GuZT [1036]. Previous thermal decomposition studies had shown that the decomposition of GuZT is a complex multi-step non-linear process that predominantly involves the formation of volatile gases such as ammonia and nitrogen and a non-volatile residue that subsequently decomposes to form higher molecular weight products. Bis(guanidinium) 5,5'-azotetrazolate can be used as a gas generant in airbag inflators in place of, or along with, other high-nitrogen compounds, potentially using copper diammine dinitrate as the oxidizer [1037–1040].

#### 14.10.5 Bis(aminoguanidinium) 5,5'-Azotetrazolate

Bis(aminoguanidinium) 5,5'-azotetrazolate (AGZT) and bis(diaminoguanidinium) 5,5'-azotetrazolate (DAGZT) are high-nitrogen compounds with very high nitrogen content (AGZT 80.22% N, oxygen balance –76.4%; DAGZT 81.36% N, oxygen balance –74.4%). However, due to their shock and friction sensitivity, they are not likely to find widespread uses as gas generant or propellant additives. GuZT is thermally more stable and TAGZT contains more nitrogen.

Some of the properties of AGZT and DAGZT are summarized in Table 66. Figure 24 provides a comparison of thermal stabilities of the various guanidinium and guanidinium derivative azotetrazolate salts.

Some of the properties of bis(triaminoguanidinium) 5,5'-azotetrazolate (TAGAT, TAGAZ, TAGzT) have already been described in *Encyclopedia of Liquid Fuels*, chapter “Amides and Imides.” Bis(triaminoguanidinium) 5,5'-azotetrazolate [which is also called di(triaminoguanidinium) 5,5'-azotetrazolate, TAGzT, TAGAT,  $C_4H_{18}N_{22}$ ,  $M = 374.34 \text{ g/mol} = 2.6714 \text{ mol/kg}$ ] is a unique energetic high-nitrogen compound that has received a lot of attention during the past two decades. TAGzT is also described as a carbonohydrazone dihydrazide (TAG), compound with 5,5'-(1,2-diazenediyl)bis[2H-tetrazole] (2:1) (azotetrazole),  $C_2H_2N_{10} \bullet 2CH_8N_6$ , CAS RN [2165-23-3].

##### 14.10.5.1 Preparation of TAGzT

The synthesis of bis-(triaminoguanidinium)-5,5'-azotetrazolate (TAGzT) by a two-step method with 5-aminotetrazole (5-AT) as the starting material has been improved [1032]. First sodium-5,5'-azotetrazolate pentahydrate was synthesized by oxidizing 5-AT with potassium permanganate in 15% aqueous sodium hydroxide solution with a yield of 75.6%. Then cation replacement between sodium-5,5'-azotetrazolate pentahydrate and TAGN gave TAGZT with a yield of 73.3%. The melting point of the material obtained was 469–470 K (196–197°C), which was in agreement with literature data. The structure of the TAGZT crystal was further characterized by  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, FTIR, and elemental analysis.

The manufacture of bis(triaminoguanidinium) azotetrazolate (TAGzT), along with its precursor which is sodium azotetrazolate pentahydrate (NaZT), has been scaled up at the NSWC-IHD. In 2003, the NSWC-IHD successfully validated both the NaZT and

TAGzT 100-gallon batch scale processes, and in 2006, the TAGzT process was optimized to improve operational safety and to maximize the product yield [1041].

TAGzT normally crystallizes in long needle-like crystals that present manufacturing challenges. TAGzT's crystal habit results in low packing densities and creates challenges in the process, starting from mixing through to extrusion. Recrystallizing the existing TAGzT needle-like structures to various particle sizes and shapes had to be conducted to improve the morphology of the crystals for propellant formulations.

#### 14.10.5.2 Physical Properties of TAGzT

The calculated enthalpy of formation of bis(triaminoguanidinium) 5,5'-azotetrazolate is +2908 kJ/kg = +1089 kJ/mol, its melting point is 482 K = 209 °C (with decomposition), and its density is 1.60 g/cm<sup>3</sup>. Another source gives the enthalpy of formation of TAGzT as +1075 kJ/mol = +257 kcal/mol [1023]. Table 66 is a summary of the properties of TAGzT with other high-nitrogen compounds and RDX for comparison.

**Table 66:** Properties of high-nitrogen explosives based on tetrazole derivatives.

Data source: [1042].

The properties of guanidinium and mono-, di-, and tri-aminoguanidinium 5,5'-azotetrazolates and bis(azidoformamidinium) 5,5'-azotetrazolate (AFZT) are summarized in Table 67.

#### 14.10.5.3 Molecular Structure of TAGzT

Bis(triaminoguanidinium) bis(5-azotetrazolate) (TAGzT) crystallizes in the centrosymmetric monoclinic space group  $P2_1/n$  with unit-cell parameters  $a = 3.962(1)$  Å,  $b = 15.019(2)$  Å,  $c = 12.981(1)$  Å, and  $\beta = 95.30(2)^\circ$  [1043]. The crystal is held together by an extensive three-dimensional network of hydrogen bonds.

The room-temperature isothermal compression behavior of bis-triaminoguanidinium azotetrazolate (TAGzT) was investigated by *in-situ* Raman spectroscopy to pressures near 17 GPa [1044]. Two prominent peaks near 1370 and 1470 cm<sup>-1</sup> arise from the C—N and N=N symmetric stretches, respectively. These results, together with micro-Raman spectroscopic analyses of the recovered and decompressed samples, suggest that TAGzT does not undergo any phase transitions within this pressure range.

**14.10.5.4 Thermal Stability, Decomposition, and Compatibility of TAGzT**

STMBMS and FTICR methods were used to examine the thermal decomposition of the mixtures of TAGzT and RDX [1045]. Hydrazine that is formed in the decomposition of TAGzT undergoes a very strong and rapid reaction with RDX. At temperatures near the melting point of RDX, the reaction rate of hydrazine with RDX is faster than the rate of decomposition of RDX by itself. The main interaction between hydrazine and RDX involves the removal of the NO<sub>2</sub> groups from RDX and their reaction with hydrazine to form primarily H<sub>2</sub>O and N<sub>2</sub>O. Since the reaction of hydrazine with RDX is rapid compared to the decomposition of RDX alone, compounds that decompose to form hydrazine at a temperature near the decomposition temperature of the nitramine ingredient should be good burn rate modifiers for nitramine-based composite propellants.

The premature and slow reaction of TAGzT with other propellant ingredients such as RDX may limit the useful life of composite propellants. Using computational chemistry, attempts have been made to predict such reactions and to simulate the complex

reaction processes that control the behavior of heterogeneous energetic materials in munitions throughout their life cycle [1046].

The thermal decomposition of TAGzT in comparison to several other azotetrazolate salts was investigated by DSC [1031]. Figure 24 shows an overlay composite of several thermograms on a common temperature scale for samples heated at a heating rate of 10 K/min. The least stable salt was bis(azidoformamidinium) 5,5'-azotetrazolate (AFZT) and the most stable salt was diguanidinium azotetrazolate (GZT).

**Figure 24:** DSC thermograms of several different 5,5'-azotetrazolate salts. (Reprinted and adapted from [1031], with permission from the ©2005 American Chemical Society; permission conveyed through RightsLink.)

The burning rate, laser ignition, and flash pyrolysis (T-jump/FTIR spectroscopy) characteristics of TAGzT were determined [1047]. It was found that TAGzT exhibits one of the fastest low-pressure burning rates measured to date for an organic compound. Both the decomposition and ignition behavior of TAGzT are dominated by condensed phase reactions. T-jump/FTIR spectroscopy indicated that condensed phase reactions release about 65% of the energy, which helps to explain the high burning rate at low pressure.

Data collected with simultaneous TGA-modulated beam MS and FTICR MS methods were used to construct a general qualitative decomposition model of TAGzT that captures the major steps that control the thermal decomposition of TAGzT [1048]. The analysis showed that four primary reaction pathways control the decomposition of TAGzT. The first pathway describes the initial decomposition of TAGzT to form triaminoguanidine (TAG) in the gas phase and azotetrazolate (AT). The second pathway represents the decomposition of TAG in the gas phase to form ammonia, HCN, N<sub>2</sub>,

and hydrazine. The third pathway is the decomposition of the molecule formed from the AT anion. AT does not evolve as a gas phase product during the decomposition of TAGzT. However, AT eliminates  $N_2$  from each tetrazolate ring, thus leaving the central core ( $C_2H_2N_6$ ) to evolve as a gaseous product. The fourth pathway involves the decomposition of a non-volatile product that forms after the decomposition of TAGzT is complete. Results of the analysis showed that both chemical and physical processes are contributing to the decomposition behavior of TAGzT and that these reaction processes are coupled, non-linear, and complex.

The compatibilities of TAGzT with the main components of propellants were studied by DSC and VST [1049]. Results showed that TAGzT has good or fair compatibility with NC, GAP, polyethylene glycol (PEG), diethylphthalate (DEP), 2-nitrodiphenylamine (2-NDPA), HMX, RDX, and aluminum powder (Al), but poor compatibility with NC+NG, *m*-dihydroxybenzene (resorcinol), and *N*-nitrodihydroxyethylamine dinitrate (DINA). TAGzT had no interactions with DEP, GAP, 2-NDPA, or Al. It had only moderate interactions with NC, HMX, or PEG but intensive interactions with DINA, resorcinol, and RDX [1050].

The thermal decomposition of TAGzT under isothermal and non-isothermal conditions in solid and liquid phases was measured and a relationship between the basicity and the thermal stability of 5,5'-azotetrazole salts was demonstrated [1023]. A boundary of possible existence of 5,5'-azotetrazole salts in terms of the basicity index  $pK_a$  was determined. Gaseous and condensed products of decomposition were analyzed and a mechanism of thermal decomposition of 5,5'-azotetrazole was proposed. The enthalpies of formation of some 5,5'-azotetrazole salts were determined and the most reliable values were chosen based on the analysis of the data obtained and those available in publications. The enthalpy of formation is +1075 kJ/mol (+257 kcal/mol).

#### 14.10.5.5 Strand Burning Rate of TAGzT

It has been shown that the replacement of a portion of RDX with TAGzT in nitramine-based propellant systems leads to a dramatic increase in the overall burning rate of the propellant. Several studies aimed at elucidating the combustion characteristics of TAGzT and its mixtures with RDX have been conducted, and some insight into the burning rate modification mechanisms have been gained as a result. Interestingly, TAGzT has been shown to not detonate at diameters of up to 1 in. Three high-nitrogen compounds [triaminoguanidinium azotetrazolate (TAGzT); 3,6-bis-nitroguanyl-1,2,4,5-tetrazine ( $NQ$ )<sub>2</sub>Tz; bis(triaminoguanidinium) 3,6-bis-nitroguanyl-1,2,4,5-tetrazinate (TAG)<sub>2</sub> ( $NQ$ )<sub>2</sub>Tz] were prepared and characterized for thermal stability, burning rate, sensitivity, and energy content [1051]. TAGzT has one of the fastest burning rates ever measured for an organic compound. 3,6-Bis-nitroguanyl-1,2,4,5-tetrazine has one of the lowest pressure exponents ever measured for a pure organic compound. A low-pressure exponent is usually indicative of condensed phase reactions dominating the combustion process. Table 68 gives

**Table 68:** Comparison of the burning rates and pressure coefficients of TAGzT and other high-nitrogen compounds.

| Compound abbreviation                   | Burning rate at 68 atm = 6.87 MPa |       | Pressure coefficient <i>n</i> |

a comparison of the burning rates and pressure coefficients of TAGzT and other high-nitrogen compounds.

TAGzT has a relatively low theoretical adiabatic decomposition flame temperature of 841 K. T-jump FTIR analysis of TAGzT decomposition products indicates that the decomposition proceeds along the following pathway:

Likewise, the decompositions of (NQ)<sub>2</sub>Tz and (TAG)<sub>2</sub>(NQ)<sub>2</sub>Tz proceed along the following pathways:

A two-phase combustion model with detailed chemistry for TAGzT with detailed output for burning rates and product distribution was developed and compared with experimental results [1052]. Semi-quantitative agreement was achieved. In particular, the experiments and model agreed that the gas phase flames plateau for long distances above the propellant surface, and equilibrium is not reached.

The common crystalline habit (needle-like structures) of TAGzT is not conducive to high bulk densities, thereby limiting the amount of propellant that can occupy a volume. In addition, the crystal habit of the material presents several challenges with manufacturing processes. Recrystallization of the existing TAGzT needle-like structures to various particle sizes and shapes had to be conducted to try to improve the morphology of the crystals for formulation.

Mixtures of 75, 50, 25, and 10% RDX with TAGzT were mixed with the non-solvent methanol, then stirred, dried, and pressed into 6.6-mm pellets [1053, 1054]. TAGzT can significantly increase the burning rate of RDX. TAGzT and RDX have a synergistic interaction during combustion. A mixture of 10 RDX/90 TAGzT burned five times faster than pure RDX and about 1.2 times faster than pure TAGzT, while having a lower pressure

sensitivity than that of both parent compounds (Figure 25). A mixture of 50 RDX/50 TAGzT had a burning rate of 3.37 cm/s at 6.7 MPa with a slope of 0.91 (which was much too high). The sea level theoretical specific impulse of such a mixture would be 232s at a chamber pressure of 6.7 MPa. This burning rate graph is very useful because it contains the data for the two pure compounds as well as data for their mixtures.

**Figure 25:** Strand burning rates of TAGzT/RDX mixtures. (Reprinted and modified from [1054], with permission from ©2007 Begell House, Inc.)

When tested for detonability, pure TAGzT exhibited no detonation propagation, even at 25.4 mm sample diameter. However, a 50:50 mix of TAGzT and RDX sustained detonation at 12.5 mm. The sensitivity properties of TAGzT and TAGzT/RDX mixtures are summarized in Table 69 in comparison to safety data for HMX.

#### 14.10.5.6 Sensitivity of TAGzT

Tables 69 and 70 provide a comparison of the sensitivity parameters of TAGzT with those of the other compounds tested and some literature data. Because TAGzT contains no oxygen, the chemistry that dominates the ignition and combustion is more centered on reactions in the condensed phase rather than on the C + O or H + O oxidation chemistry that takes place in the gas phase. The enthalpy of formation of TAGzT is +1075 kJ/mol = +257 kcal/mol. The burning rate of TAGzT was found to be one of the fastest burning compounds known to exist (Table 71), comparable to the high-nitrogen

**Table 69:** Sensitivity parameters of TAGzT in comparison with those of other energetic compounds.

compounds 3,3'-azobis(6-amino-1,2,4,5-tetrazine)-3,5-*N*-oxide (DAATO<sub>3.5</sub>) and 3,6-bis-(1*H*-1,2,3,4-tetrazol-5-ylamino)-s-tetrazine (BTATz). However, despite its remarkable combustion behavior and the fact that it has a high calculated detonation performance, it has not been found to be sensitive to shock initiation and transition to detonation, even at diameters as large as 4.1 cm (1 5/8 in.). In a large-scale gap test, and with a 4.1 cm D × 10 cm H (1.625 in. D × 4 in.) donor charge of PBX9205, the TAGzT did not detonate. The witness plate showed no dent and traces of unreacted TAGzT were found. This insensitivity to shock initiation is all the more intriguing because of TAGzT's sensitivity to impact and friction (which is roughly similar to that of HMX). Speculation into the mechanism of this behavior is open to discussion [1055]. Table 71 provides a comparison of the sensitivities and detonation velocities of TAGzT and other energetic materials.

A summary of energetic materials published lists the properties and methods for the preparation of AZT, guanidinium azotetrazolate (GuZT), and triaminoguanidinium azotetrazolate (TAGzT) [1056]. TAGzT has the advantage of being able to reduce the combusting temperature, enhancing the burning rate of propellants, and producing a lot of gas. GuZT, with the advantages of reducing the combusting temperature and producing relatively cool gases, has been widely used in gas generators.

Data Source: [1055].

#### 14.10.5.7 Applications of TAGzT

Originally, TAGzT was proposed as a source of nitrogen in pyrotechnic fire extinguishers that snuff out fires by depriving them of oxygen from the air [925, 926, 1042]. Interest has since shifted to its ability to increase the burning rate of many propellant formulations, particularly those containing nitramines.

Burn-rate modeling is critical for developing new rocket missile and gun propellants and for providing a fundamental screening tool that can result in substantial cost savings compared to missile and gun firings. The detailed chemical kinetics and the burn rate prediction of TAGzT and NC were applied to several burner-stabilized flames relevant to the combustion of solid propellants to calculate the burning rates of TAGzT, with and without a nitrate ester-based propellant [1057, 1058]. The model employed a detailed, chemical reaction mechanism containing 59 species and 368 reactions. Calculations showed that TAGzT enhances the burning rate of the base propellant over a range of pressures used for rockets and guns by a factor of three at 10 MPa.

Triaminoguanidinium 5,5'-azotetrazolate has been included in the NILE (Navy insensitive low-erosion) gun propellant mixture to reduce barrel wear. This propellant was developed at the NSWC-IHD. The NILE mixture was successfully tested as a propellant in, for example, a 105-mm howitzer [1059].

#### 14.10.6 Bis(semicarbazidium) 5,5'-Azotetrazolate

The metathesis reactions between sodium 5,5'-azotetrazolate ( $[\text{Na} + ]_2\text{ZT}^{2-}$ ) pentahydrate and 1,3-dimethyl-5-aminotetrazolium iodide, or semicarbazidium chloride in water, lead to the formation of the corresponding  $\text{ZT}^{2-}$  salts as the hydrated species **(2)** and **(4)** [1060]. The anhydrous derivatives **(1)** and **(3)** were synthesized by reaction of silver 5,5'-azotetrazolate with a suitable halogenide salt in methanol. Alternatively, the crystal water in the hydrated salts **(2)** and **(4)** can be quantitatively but slowly removed under a vacuum. This leads to a safe synthesis for compounds **(1)** and **(3)**, which does not depend on the use of highly sensitive silver salts. The formation of the salts was confirmed by analytical and spectroscopic methods. In addition to this,

the crystal structures of **(2)** and **(4)** were determined using low-temperature XRD and found to be as follows **(2)**: monoclinic  $P_2(1/n)$ ,  $a = 9.3101(3) \text{ \AA}$ ,  $b = 6.5383(2) \text{ \AA}$ ,  $c = 19.5637(5) \text{ \AA}$ ;  $\beta = 90.48(1)^\circ$ ;  $V = 1190.84(6) \text{ \AA}^3$ , and **(4)**: triclinic  $P\bar{1}$ ,  $a = 4.563(5) \text{ \AA}$ ,  $b = 7.362(5) \text{ \AA}$ ,  $c = 11.334(5) \text{ \AA}$ ;  $\alpha = 105.125(5)^\circ$ ,  $\beta = 90.48(1)^\circ$ ,  $\gamma = 102.871(5)^\circ$ ;  $V = 357.2(5) \text{ \AA}^3$ . Unfortunately, the semicarbazidium salts **(3)** and **(4)** have relatively low thermal stabilities ( $<403 \text{ K} = <130^\circ\text{C}$ ) and the tetrazolium salts **(1)** and **(2)** decompose above  $463 \text{ K} = 190^\circ\text{C}$ . All four compounds can be classified as insensitive and have good explosive performances: **(1)**  $P = 19.0 \text{ GPa}$  and  $v_{\text{det.}} = 7667 \text{ m/s}$ ; **(2)**  $P = 25.1 \text{ GPa}$  and  $v_{\text{det.}} = 8585 \text{ m/s}$ ; **(3)**  $P = 23.4 \text{ GPa}$  and  $v_{\text{det.}} = 8125 \text{ m/s}$ ; and **(4)**  $P = 20.0 \text{ GPa}$  and  $v_{\text{det.}} = 7694 \text{ m/s}$ . All release (mainly) environmentally benign gases when they decompose.

#### 14.10.7 Bis(azidoformamidinium) 5,5'-Azotetrazolate

Bis(azidoformamidinium) 5,5'-azotetrazolate (AFZT),  $\text{C}_4\text{H}_8\text{N}_{20}$ ,  $[\text{H}_2\text{N}^+=\text{C}(\text{N}_3)\text{NH}_2]_2=[\text{AT}^{2-}]$ ,  $M = 336.24 \text{ g/mol}$ , 83.31% N, OB = -57.1%, can be prepared by the reaction of the respective azidoformamidinium nitrate with a hot aqueous solution of Na2AT followed by the fractional crystallization of the azotetrazolate [1031]. An alternate method is the diazotization of aminoguanidinium 5,5'-azotetrazolate (AGZTH), where ethyl nitrite is slowly added to a warm solution ( $313 \text{ K} = 40^\circ\text{C}$ ) of AGZTH in water. The solution was kept at  $313 \text{ K} = 40^\circ\text{C}$  for 1 h and then cooled to  $278 \text{ K} = 5^\circ\text{C}$ . Orange AFZT crystals were obtained, separated by filtration, and washed with EtOH and Et<sub>2</sub>O. During the crystallization process, the formation of nitrogen was observed. The physical and sensitivity properties of AFZT in comparison to several other azotetrazolate salts have already been summarized in Table 67. AFZT melts at  $407 \text{ K}$  ( $134^\circ\text{C}$ ) with decomposition. The thermal decomposition of AFZT in comparison to several other azotetrazolate salts was investigated by DSC. Figure 24 demonstrates an overlay composite of several thermograms on a common temperature scale for samples heated at a heating rate of  $10 \text{ K/min}$ . The least stable salt was AFZT, and the most stable salt was GZT.

#### 14.10.8 5,5'-Azotetrazolates of Heterocyclic Cations

The preparation of 1,3-dimethyl-5-aminotetrazolium 5,5'-azotetrazolate was already described in a previous section. Salts of 5,5'-azotetrazolate with 5-aminotetrazole and 2,4,6-triamino-s-triazine cations were synthesized and evaluated as potential ingredients for gun propellants [1061]. These salts were characterized by density measurement, NMR and IR spectroscopy, and DSC. In the DSC, 5-aminotetrazolium 5,5'-azotetrazolate began to decompose at  $407.4 \text{ K} = 134.3^\circ\text{C}$  with a peak exotherm at  $443 \text{ K} = 170^\circ\text{C}$ . 2,4,6-Triamino-s-triazinium 5,5'-azotetrazolate began to decompose at  $521.4 \text{ K} = 248.3^\circ\text{C}$  with a peak exotherm at  $543 \text{ K} = 270^\circ\text{C}$ . Their reactions to mechanical stimuli were also determined by small-scale sensitivity testing, small-scale shock reactivity testing, and small-scale internal blast testing.

#### 14.10.9 Other Azotetrazole Derivatives

Attempts have been made (at least on paper) to improve the stability of azotetrazole by adding stabilizing substituents to one or both of the tetrazole rings. It was hoped that such substitutions would result in a more stable resonance structure of the electron cloud-connected via the  $\text{—N=N—}$  bridge.

The potential curves of the decomposition of 1-methyl-5-azotetrazole (1-MAT) and 2-methyl-5-azotetrazole (2-MAT) were calculated by a quantum chemistry method [1062]. The activation energies of decomposition are 245.9 and 183.2 kJ/mol, respectively. Thermal stability and decomposition mechanisms have been studied based on ground state and dynamic conditions. The calculated results indicated that the thermal stability of 1-MAT is better than that of 2-MAT. Ring-opening is the first step in decomposition.

The properties of 1,1'-dimethyl-5,5'-azotetrazole (DMATA) and its influence on the theoretical specific impulse, burning rate, pressure exponent, and chemical stability of modified double-base propellants have been studied [1063]. It was discovered that DMATA may increase the specific gas volume and burning rate of propellants.

The potential curves of thermal decomposition for 1,1'-dimethyl-5, 5'-azotetrazole (1,1'-DM-5,5'-AT) and 2,2'-dimethyl-5,5'-azotetrazole (2,2'-DM-5,5'-AT) were calculated by use of *ab initio* calculation by a quantum chemistry method and the activation energies of two-step decomposition reactions were predicted [1064]. The ring-opening reaction controls the decomposition rate. The predicted thermal stability of 1,1'-DM-5,5'-AT is better than that of 2,2'-DM-5,5'-AT. The structures of 1,1'-DM-5,5'-AT and 2,2'-DM-5,5'-AT are planar, the bond lengths in the tetrazole rings have aromatic characteristics, and the tetrazole ring satisfies the  $4n+2$  rule [1064]. The calculated aromaticity index, net charge in the ring, and relation energy of electrons revealed that the predicted thermal stability of 1,1'-DM-5,5'-AT is better than that of 2,2'-DM-5,5'-AT, in accordance with experiment results [1065, 1066].

To prepare for the eventual future synthesis of an as yet unknown 2,2'-bis-(trinitromethyl)-5,5'-azotetrazole compound, a DFT method was used to calculate the molecular structure [1067]. Its properties, such as its electronic structure, IR spectrum, HOF, thermodynamic properties, and crystal structure were predicted by computer. This compound is most likely to crystallize in the  $P2_1$  space group, and the corresponding cell parameters would be  $a = 5.46 \text{ \AA}$ ,  $b = 9.72 \text{ \AA}$ ,  $c = 14.05 \text{ \AA}$ ,  $\alpha = 90^\circ$ ,  $\beta = 90^\circ$ ,  $\gamma = 90^\circ$ , and  $Z = 2$ . The detonation velocity and pressure were also estimated by using the empirical K-J equations and were predicted to be 8.28 km/s and 31.61 GPa respectively. The oxygen balance of this compound is +13.79%, which indicates that it could serve as an oxidizer. BDE calculations showed that the  $\text{C(13)—N(21)O}_2$  and  $\text{C(14)—N(30)O}_2$  bonds are the weak bond locations where thermal decomposition is likely to start.

The structures, IR spectra, and cation stability of guanidinium (GuZT), aminoguanidinium (AGZT), diaminoguanidinium (DAGZT), triaminoguanidinium

(TAGZT), azidoformamidineum (AFZT), ammonium (AZT), and hydrazinium (HZT) 5,5'-azotetrazolate were investigated by dynamic functional theory calculations [1068]. The calculated results indicated that the carbon and nitrogen atoms of the cations in seven non-metallic salts are  $sp^2$  hybrid atoms, and the ranges of characteristic absorption peaks in IR spectra of the seven non-metallic salts were approximative consistent. All their cations are stable, and their stabilities decreased with the increase in their nitrogen contents. To characterize their infrared spectra, the frequency analytical calculations were performed for the seven salts at the same level of theory. The cation decompositions of seven salts were calculated to predict the cation stability.

1,1'-Diamino-5,5'-azotetrazole, which was obtained from the reaction of 1,5-diaminotetrazole with acetone, sodium dichloroisocyanurate, and acetic acid, respectively, was well characterized [1069]. Its structure was confirmed by X-ray crystallography and the thermal stability and explosive performance were also investigated.

1,1'-Diamino-5,5'-azotetrazole, also known as 5-[(1-amino-1 $\lambda$ 5,2,3,4-tetrazacyclopenta-1,3-dien-5-yl)azo]-1 $\lambda$ -5,2,3,4-tetrazacyclopenta-1,3-dien-1-amine,  $C_2H_6N_{12}$ , DAZT, can be synthesized using acetic acid and 1,1'-diisopropylideneamino-5,5'-azotetrazole as the raw material [1070]. The maximum yield was 97.6% under optimum reaction conditions. The thermal decomposition behavior of DAZT was investigated by TG-DSC and DTA techniques. In the DTA at  $5^\circ/\text{min}$ , the melting endotherm was at 427–439 K (154–166  $^\circ\text{C}$ ), and the peak temperature was 432.94 K (159.79  $^\circ\text{C}$ ) with no obvious mass loss, and the melting enthalpy was 72.35 J/g. The exotherm was at 439–458 K (166–185  $^\circ\text{C}$ ) with a peak temperature of 451.91 K (178.76  $^\circ\text{C}$ ) and a decomposition enthalpy of 1024.83 J/g. The activation energy of decomposition was 138.57 kJ/mol.

### 14.11 Hydrazotetrazole Derivatives

Hydrazotetrazole, also known as 1,2-bis(5*H*-tetrazol-5-yl)hydrazine, is a hydrazine derivative with two tetrazolyl rings attached to two opposite nitrogen atoms. This compound has also been called 1,2-ditetrazolylhydrazine or 5,5'-hydrazinebistetrazole or bistetrazolohydrazine or *N,N'*-bistetrazolohydrazine but these are not the correct names.

5,5'-Hydrazotetrazole

The enthalpy of formation of 5,5'-hydrazotetrazole,  $C_2H_4N_{10}$ ,  $M = 168.12$  g/mol, is  $+804$  cal/g =  $+135$  kcal/mol =  $+565$  kJ/mol. It contains 83.3% nitrogen. The density of 5,5'-hydrazotetrazole is  $1.841$  g/cm<sup>3</sup> and the predicted detonation velocity is  $8523$  m/s with a detonation pressure of  $27.7$  GPa.

Solutions of *N,N'*-azobistetrazolate salts in anhydrous hydrazine were reduced to salts of *N,N'*-bistetrazolohydrazine [1071]. Several salts of this highly energetic, nitrogen-rich anion were prepared this way and characterized by elemental analysis, IR, and Raman and multi-nuclear NMR spectroscopy.

In the DSC, and with a heating rate of  $5^\circ/\text{min.}$ , 5,5'-hydrazotetrazole began to decompose at  $483$  K ( $210^\circ\text{C}$ ). It decomposed violently at  $506$  K ( $233^\circ\text{C}$ ) [1072], which was its peak temperature also. The enthalpy of reaction was  $632.1$  J/g. The activation energy of 5,5'-hydrazotetrazole decomposition was  $230.8$  kJ/mol and the pre-exponential factor was  $3.43 \times 10^{23} \text{ s}^{-1}$ . The decomposition enthalpy of HBT was  $576.45$  J/g when the heating rate was  $5^\circ/\text{min.}$  In the TGA, the maximum weight loss temperature was from  $493$  to  $506$  K ( $220$  to  $233^\circ\text{C}$ ) with heating rates from  $2$  to  $20^\circ\text{C}/\text{min.}$

Most 5,5'-hydrazinobistetrazole derivatives reported in the literature are sensitive to oxidation and react with atmospheric oxygen to yield the corresponding 5,5'-azobistetrazolates as time goes by. A free acid 5,5'-hydrazinobistetrazole (HBT) was prepared which seemed to be stable on air for extended periods of time [1073]. The compound was fully characterized by analytical and spectroscopic methods and its structure was determined by XRD. The HOF is  $+414$  kJ/mol. The predicted detonation velocity is  $8523$  m/s and the detonation pressure is  $27.7$  GPa. It has a low impact sensitivity of  $>30$  J, friction sensitivity of  $\sim 108$  N, and was used as a starting material for the synthesis of other 5,5'-azobistetrazolates [551, 1074, 1075].

A series of nitrogen-rich molecules, such as hydrazinobistetrazole, 5-aminotetrazolium nitrate, bis(2,2,2-trinitroethyl)-hydrazodicarboxylate, RDX, TNT, melamine, sucrose, and L-glutamine were studied using laser-induced breakdown spectroscopy

1-(1H-tetrazol-5-yl)pentazole

1-(2H-Tetrazol-5-yl)pentazole

Tetrazolylpentazole was identified as an intermediate in the reaction of tetrazolediazonium chloride with lithium azide by low-temperature  $^{15}\text{N}$  NMR spectroscopy. The decomposition of  $^{15}\text{N}$ -labeled tetrazolylpentazole to form  $^{15}\text{N}$ -labeled tetrazole azides and dinitrogen was followed by low-temperature  $^{15}\text{N}$  NMR spectroscopy. The structures of the species involved in this decomposition were optimized by computational methods at different levels of theory, and the structures of the transition states and the activation barriers for the decomposition were identified. The stability of tetrazolylpentazole and its corresponding anion pentazolyltetrazolate was calculated to be 63–67 kJ/mol (15–16 kcal/mol) and 88–92 kJ/mol (21–22 kcal/mol), respectively, and was later found by a different method to be more like 48 kJ/mol (11.4 kcal/mol) and 74 kJ/mol (17.7 kcal/mol), respectively [862, 1079]. The activation energy for the decomposition increased while the decomposition energy of the substituted pentazole decreased with greater electron-donating character of the substituent of the pentazole. Thus, anionic pentazoles were predicted to be more stable than neutral pentazoles. Methylpentazole was predicted to be among the most stable pentazoles even though it does not contain an aromatic system.

High-nitrogen compounds such as 3,6-bis(1*H*-1,2,3,4-tetrazol-5-ylamino)-s-tetrazine (BTATz) or mixed *N*-oxides of 3,3'-azobis(6-amino-1,2,4,5-tetrazine) (DAATO3.5) can be used as working fluids in electrical discharge micro-thrusters [1080].

Aminoguanidine is a useful intermediate for numerous high-nitrogen compounds. Aminoguanidinium sulfate or aminoguanidinium hydrogen carbonate and sodium nitrite react in a solution slightly acidified with acetic acid to form “tetracene” through aminotetrazole and its diazo salt [1081, 1082]:

The more accurate designation for this compound is 1-(5-tetrazolyl)-4-guanyltetrazene. It forms shock-sensitive heavy-metal salts with silver or copper.

Tetracene (tetrazene), 1-[2-(1*H*-tetrazol-5-ylimino)hydrazino]guanidine, 4-(1*H*-tetrazol-5-yl)tetraaz-1-ene-1-carboximidamide,  $C_2H_6N_{10}$ , CAS RN [539-57-1],  $M = 170.136$  g/mol, is a hydrazine-derived primary explosive with a strongly positive enthalpy of formation ( $+1005$  kJ/kg =  $+189$  kJ/mol). Tetracene is slightly more impact-sensitive than mercury fulminate. The molecular structure of tetracene, a primary explosive with a tetrazole ring, had been the subject of many debates until a more detailed X-ray and molecular structure study was conducted [1083] and was supported by Complete Neglect of Differential Overlap (CNDO) quantum-mechanical calculations [1084] that showed that the primary explosive tetracene exists in the solid state as the zwitterion form of 1-amino-1[(1*H*-tetrazol-5-yl)azo]guanidine hydrate.

The positive charge can be on either of the two nitrogen atoms or even on the carbon atom of the guanidinium group. This resonance structure gives the compound unusual stability; thus both the Hofmann [1085] and Patinkin [1081] structures are wrong. The thermal decomposition of tetracene was modeled by computer calculations [1086].

A family of nitrogen-rich energetic tetrazoles, di(1*H*-tetrazol-5-yl)methanone oxime and 5,5'-(hydrazonomethylene)bis(1*H*-tetrazole), was synthesized from inexpensive starting materials [1087]. These tetrazoles had excellent thermal stabilities and very high nitrogen contents as well as acceptable impact and friction sensitivities and were employed as precursors to nitrogen-rich energetic salts. The hydrazinium and hydroxyl ammonium salts of 5,5'-(hydrazonomethylene)bis(1*H*-tetrazole) exhibited excellent detonation velocities (9050 and 8839 m/s, respectively) as well as very good detonation pressures and thermal stabilities.

A not yet synthesized 8-N conjoined energetic compound 1-amino-tetrazolo-[4,5-b]tetrazole, tetrazolo[1,5-e]tetrazol-4-amine has been designed using a DFT method on a computer [1088]. It looks promising when seen on the computer screen, however, the question arises of whether it can actually be synthesized? The optimized geometry, vibration analysis (including thermochemistry and IR spectrum), NMR data, NBOs and charges, and the electrostatic potential were calculated in order to inspect the electronic structure properties and interactions of chemical bonds. Properties such as density, enthalpy of formation considering the enthalpy of phase transition and detonation performance could be predicted. The detonation velocity and pressure of this compound were predicted to be 8.90 km/s and 33.83 GPa, respectively. The compound had a highly positive HOF (+792 kJ/mol = +189 kcal/mol) but the question arose of whether it will decompose before it can be synthesized?

1-Amino-tetrazolo-[4,5-b]tetrazole

#### 14.13.1 Polymeric Tetrazole Derivatives

5-Phenyl-1H-tetrazole can be obtained from phenylcyanide and sodium azide with trimethylammonium chloride [184]. Instead of azido groups in GAP (poly[(azidomethyl)ethylene oxide], GAP), similar energetic binders can be obtained by attaching tetrazolyl groups to the polymer chain by a Diels-Alder reaction. A new, safe, and sustainable process to produce tetrazoles was designed; it achieved high yields under mild conditions.

Nitrogen-rich polymers can be obtained either by radical polymerization (poly(methyl-1-(1-vinyl-1H-tetrazol-5-yl)hydrazine)) or polycondensation reactions [1089]. The nitrogen-rich polymers prepared by polycondensation reactions of the 1,1-methyl-1H-tetrazolylhydrazine possessed high thermal stability (> 513 K = > 240 °C) and were insensitive towards impact and friction. The advantage of these polymers is that the

functional groups are stabilized by the formed carbamates, reducing the chemical reactivity. Nevertheless, the NH-proton of the carbamate structure was able to form hydrogen bridges, leading to increased adhesion forces between the energetic filler and the polymer. The energetic polymers formed by radical polymerization bears hydrazine moieties that increase the solubility in acids, along with possible adhesion forces with energetic fillers. The 5-azido-1*H*-tetrazoles were prepared by diazotation of tetrazolyl hydrazines.

A polyvinyl(tetrazole) can be formed by a water-based method and used as gas generant for the inflation of airbags [1090]. Preferred vinyl tetrazoles include 5-amino-1-vinyltetrazole, poly(5-vinyltetrazole), poly(2-methyl-5-vinyltetrazole), and poly(1-vinyltetrazole).

Miscible polymer pairs can be formed with an energetic polymer, such as poly(2-methyl-5-vinyl tetrazole) (PMVT), and a non-energetic polymer PEG with the molecular mass (weight) of between 1000 to 4000. This polymer blend (PEG/PMVT) can be formed from an acetonitrile solution upon removal of the solvent in which both polymers were soluble [1091]. The blend can also be precipitated by adding non-solvent-like hexane to a solution of PEG/PMVT in acetonitrile at or below 0°C. With PEG E1000, blends have been formed with PEG:PMVT ratios of 1:1 to 1:1.8 by weight. This blend has been characterized with regard to its unique glass transition temperature,  $T_g$ , as well as its ability to form transparent films. Interaction between chains in the form of weak C—H...O hydrogen bonding has been identified from IR band broadening. A PMVT/GAP polymer blend can also be formed in a narrow range of temperatures. This polymer blend is useful as a desensitizing energetic binder for propellants and PBX. A PBX composition containing 91 mass-% RDX and 9% PEG-PMVT polymer blend had a drop-weight-impact sensitivity better than Comp B.

Poly(5-amino-1-vinyl) tetrazole and poly(2-methyl-5-vinyltetrazole) are nitrogen-rich polymers that have been patented as nitrogen-rich energetic binders for solid propellants and gas generants [1092]. Poly(methylvinyltetrazol), PMVT,  $(C_4N_4H_6)_n$ , is a high-enthalpy polymer with high nitrogen content (~46%N). It has an enthalpy of formation of  $\Delta H_f = +1255 \text{ kJ/kg}$  and a density of  $\rho = 1.28 \text{ g/cm}^3$ .

#### 14.13.2 Record-Length Catenated Nitrogen Chains in Heterocyclic Compounds

As an outgrowth of the development effort of high-nitrogen and high-energy compounds, a competitive effort has been started to synthesize molecules with very long chains of catenated nitrogen atoms. In most cases, these chains are stabilized by aromaticity in the participating rings. The rings are mostly five-membered rings and, at the time of writing this, the maximum number of nitrogens arranged in one “hand-holding” sequence is eleven.

The construction of a catenated nitrogen chain of eight nitrogen atoms was achieved through the oxidative azo coupling of an N—NH<sub>2</sub> moiety. The amino group

attached to a triazole ring was first transformed into a diazonium ion under acidic conditions. A subsequent nucleophilic attack of the amino group of the 1-amino-1,2,3-triazole on this diazonium cation produced the desired structure containing eight catenated nitrogen atoms. The resulting N8 compound, 1,1'-azobis-1,2,3-triazole, had a nitrogen content of 68.27% [258].

The synthesis of N10 has already been described in preceding chapters [999, 1000]. Based on the thermal decomposition mechanism of N10, the probability of being successful in attempting to synthesize N12 and N14 was explored. These longer nitrogen chain compounds that have higher nitrogen contents than N10 would make good HEDMs. By comparing their energetic barriers with the corresponding primary N<sub>2</sub>-elimination reaction of N10, it was concluded that the predicted structures could theoretically exist at room temperature. As a first step in this direction, a stable catenated N11 salt has been synthesized by an azo coupling reaction from 1,5-diaminotetrazole [1001]. Researchers have synthesized heterocyclic compounds with highly catenated chains of nitrogen atoms through a strategy of oxidative azo coupling of N—NH<sub>2</sub> moieties [1093].

It is difficult to predict the exact number of nitrogen atoms that will finally be the limit to the catenated nitrogen atom chains, but indications are that the recent advances in the synthesis of such extended nitrogen chains will definitely open new methods for the synthesis of new high-nitrogen materials [1094]. Computational work by theoreticians is setting the stage to guide the hands of synthetic chemists.

An N5-linear energetic moiety of pentazadiene has been constructed from a triazene precursor. Thus, a series of 1,3,5-tri(tetrazol-5-yl)pentaza-1,4-dienes have been synthesized in moderate to high yields by treatment of 1,3-bis(tetrazol-5-yl)-triazenes with 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride under mild conditions. All compounds were fully characterized using IR spectroscopy, <sup>1</sup>H and <sup>13</sup>C NMR spectroscopy, and DSC. Calculations predicted that the methyltetrazole homolog has a HOF of 1699 kJ/mol.

## 15 Furoxans and Oxazoles

### 15.1 Furoxan

Furoxan, 1,2,5-oxadiazole 2-oxide, furazan 2-oxide, CAS RN [497-27-8],  $M = 86.049$  g/mol, is a heterocycle of the isoxazole family and an amine *N*-oxide derivative of furazan.

Furoxan and its derivatives are actively researched as potential high-density explosives. Furoxans can be formed by the dimerization of nitrile oxides. Many energetic compounds have been examined that have other rings attached to the furoxan ring [1095].

Aminonitrobenzodifuroxan can be synthesized from 3,5-dinitrobenzoic acid [1096]. Another energetic furoxan is 3,4-dinitrofurazanofuroxan, which was crystallized from acetone and water, and was characterized by XRD, elemental analyses, and FTIR [1097]. The crystals were orthorhombic, space group *P*222, with crystal unit cell parameters of  $a = 1.0746(7)$  nm,  $b = 1.5099(10)$  nm,  $c = 0.6596(4)$  nm,  $V = 1.0702(1)$  nm<sup>3</sup>,  $Z = 4$ , and  $\rho_{\text{XRD}} = 1.937$  g/cm<sup>3</sup>.

### 15.2 Furazans

Furazans derive their name from furan by replacing one or two  $-\text{CH}=\text{}$  groups in the five-membered ring with  $-\text{N}=\text{}$  atoms. The oxygen atom remains in the ring. Various methods for the synthesis of high-energy-density compounds were published that included the use of aminofurazan as the precursor. Oxidation, nitration, diazotization, condensation, and nucleophilic displacement reactions were used to reinforce the energy content of the molecule.

Furazan, 1-oxa-2,5-diazole, CAS RN [288-37-9], is a heterocyclic aromatic organic compound consisting of a five-atom ring containing one oxygen and two nitrogen atoms. It boils at  $371\text{ K} = 98^\circ\text{C}$ . Furazan and its derivatives can be obtained from the oxime derivatives of 1,2-diketones.

3,4-Diaminofurazan, 1,2,5-oxadiazole-3,4-diamine, DAF, has been an important precursor to a series of furazan-based HEDMs that are of interest as both propellant and explosive ingredients. This compound has already been described in an earlier section in this chapter.

The oxidation of DAF with  $\text{H}_2\text{O}_2$  yields 4,4-diamino-3,3-azoxyfurazan,  $\text{C}_4\text{H}_4\text{N}_8\text{O}_3$ , DAAF, CAS RN [78644-89-0],  $M = 212.126 \text{ g/mol}$ , or 4,4-diamino-3,3-azofurazan,  $\text{C}_4\text{H}_4\text{N}_8\text{O}_2$ , DAAzF, CAS RN [1248439-96-4],  $M = 196.127 \text{ g/mol}$  [661].

4,4-Diamino-3,3-azoxyfurazan (DAAF)

4,4-Diamino-3,3-azofurazan (DAAzF)

DAAF has a crystal density of  $1.747 \text{ g/cm}^3$ ,  $\Delta H_f = +443 \text{ kJ/mol} = +106 \text{ kcal/mol}$  and a drop weight sensitivity with a 50% point at  $H_{50} > 320 \text{ cm}$  (with a 2.5-kg weight in the Type 12 machine) [672].

DAAF and 4,4'-diamino-3,3'-azofurazan (DAAzF) are obtained from the furazan precursor 3,4-diaminofurazan (DAF), which readily oxidizes to form mixtures of DAAF, DAAzF, and 3-amino-4-nitrofurazan. The first two were examined for future roles in insensitive explosive applications. Despite its large internal energy (measured enthalpy of formation =  $+536 \text{ kJ/mol}$ ), DAAzF is insensitive to impact ( $H_{50} > 320 \text{ cm}$ , Type 12), spark ( $> 0.36 \text{ J}$ ), and friction ( $> 36 \text{ kg}$ , BAM). When compared to DAAF, DAAzF has a lower detonation velocity and CJ pressure, presumably because the increase in the HOF is not sufficient to offset the loss of the one azoxy oxygen in the molecule. DAAzF has a DSC onset comparable to that of HNS ( $588 \text{ K} = 315^\circ\text{C}$ ) and a higher calculated  $\Delta H_f$  ( $+611 \text{ kJ/mol}$ ) than DAAF.

Neither DAAF nor DAAzF can be initiated by laboratory impact drop tests. Nonetheless, both (in some respect) have better explosive performances than 1,3,5-triamino-2,4,6-trinitrobenzene (TATB), and therefore meet the current standards for insensitive high explosives. The thermal stability of DAAzF is equal to that of hexanitrostilbene (HNS), yet DAAzF is a better explosive. The tetrazole derivative 3,6-bis-(1*H*-1,2,3,4-tetrazol-5-ylamino)-*s*-tetrazine (BTATz) was measured to have

exceptional positive HOFs, yet it is insensitive to explosive initiation. Because of its high burn rate and low sensitivity to pressure, this material is of great interest as a rocket propellant and gas generant additive. The vapor pressure of DAAzF is listed in Table 72.

**Table 72:** Thermodynamic data on the evaporation and sublimation of DAAzF.

| State of matter | Temp. interval<br>K | Temperature dependence of pressure above condensed phase<br>(pressure in atm, temperature in kelvin) | Heat of evaporation (or sublimation)<br>kJ/mol |
|-----------------|---------------------|------------------------------------------------------------------------------------------------------|------------------------------------------------|
| Solid           | 523–599             | $\ln P = 18.610 - 11963.6/T$                                                                         | (99.6)                                         |

Data source: [683].

The thermal decomposition of 3,3'-diamino-4,4'-azofurazan (DAAzF) was investigated under isothermal conditions at 473–593 K (200–320 °C) using a thin-walled glass manometer of the compensation type. The kinetic rate equation for the thermal decomposition of molten DAAzF in the temperature range 830–1180 K is [484, 683]:

$$k = 10^{8.66} \exp(-16680/T)$$

where  $k$  is the rate constant in  $\text{s}^{-1}$  and  $T$  is the temperature in kelvin. The kinetic rate equation of DAAzF decomposition predominantly in the solid state was

$$k = 5.0 \times 10^{11} \exp(-21320/T)$$

and in the gas phase

$$k = 3.3 \times 10^{12} \exp(-21020/T).$$

Based on the burning rate and thermocouple measurement data, rate constants of DAAzF decomposition in the molten layer at 873–1073 K (600–800 °C) have been derived from a condensed-phase combustion model and can be expressed by

$$k = 4.6 \times 10^8 \exp(-16680/T),$$

which is in good agreement with kinetic data obtained in solution at 508–533 K (235–260 °C). The mechanism of DAAzF thermolysis and combustion includes the initial rupture of the C–N bond between the azo-group and furazan ring with subsequent nitrogen evolution and decomposition of the heterocyclic ring. In the combustion wave, the heat released from the decomposition of the stable furazan ring follows the heat release from azo-group decomposition, resulting in a distinct two-stage flame structure. For these calculations, the average specific heat, thermal diffusivity, and sample density were taken as  $1.67 \text{ kJ kg}^{-1} \text{ K}^{-1}$  ( $0.4 \text{ cal g}^{-1} \text{ K}^{-1}$ ),  $1.4 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$ , and  $1.67 \text{ g/cm}^3$ , respectively. The heat of reaction in the melt,  $Q$ , was taken as  $1840 \text{ kJ/kg}$  ( $440 \text{ cal/g}$ ) or

86 kcal/mol). The heat of melting,  $\Delta H_{\text{fus}}$  (35.1 kJ/mol or 8.4 kcal/mol or 43 cal/g) was obtained as the difference between heats of sublimation and evaporation.

As can be seen in Figure 26, kinetic parameters of DAAzF decomposition derived from the combustion model

$$k = 10^{8.66} \exp(-16680/T)$$

are in good agreement with the experimental rate constants of DAAzF decomposition in the solution at lower temperatures. Using rate constants of DAAzF decomposition derived from the combustion model in the temperature interval of 873–1073 K (600–800 °C) and data on the DAAzF decomposition in solution at low temperatures, one can calculate the kinetics of DAAzF decomposition in the widened temperature interval 523–1073 K (250–800 °C):

$$k = 10^{7.61} \exp(-15570/T).$$

The activation energy of DAAzF decomposition in the liquid state in this temperature interval is 129.4 kJ/mol (32.9 kcal/mol).

Thirteen different furazan-functionalized tetrazolate-based energetic salts were prepared by direct treatment of neutral 4-amino-3-(5-tetrazole)furazan and a Lewis base or by simple metathesis reactions of its barium salt formed *in-situ* with the corresponding sulfate salts in an aqueous solution [1098]. Physical properties, such as melting point, thermal stability, density, hypergolicity, and sensitivity to shock were measured. The relationship between their structures and these properties was also determined. Most of the salts exhibited better thermal stability than their 5-nitrotetrazolate and 5-nitraminotetrazolate analogues as well as other furazan-based salts. The structures of representative aminoguanidinium, triaminoguanidinium, and 1,4-dimethyl-5-aminotetrazolium salts were further confirmed by single-crystal XRD and their densities, enthalpies of formation, detonation pressures and velocities, and specific impulses were calculated.

Macrocyclic derivatives with diazenfurazanyl fragments were synthesized by oxidative macrocyclocondensation of various diamines of the furazan series as follows: 3,4-diaminofurazan 4,4-diamino-3,3-diazenofurazan and diaminodifurazanyl under the action of different oxidizers [1099]. Some of the compounds had good thermal stability (about 473 K [200 °C]), high enthalpy of formation 2920–5021 kJ/kg (700–1200 kcal/kg), and high density (1.7–1.93 g/cm<sup>3</sup>).

DFT and VBT calculations have been performed to study the crystal densities, HOFs, energetic properties, thermodynamics of formation, and impact sensitivity for the salts composed of heterocycle-functionalized nitraminofurazanate anions and triaminoguanidinium cation [1100]. The results showed that the triaminoguanidinium nitraminofurazanate-based salts have high densities and positive enthalpies of formation. The substitution of the oxygen-containing substituent (–NO<sub>2</sub> or –C(NO<sub>2</sub>)<sub>3</sub>) helps enhance the densities and detonation properties of the nitraminofurazanate-based salts. The substitution of –C(NO<sub>2</sub>)<sub>3</sub> offers the best performance. Incorporating the conjugated bridge –N–N– or –N–N–N–N– into the heterocycle-functionalized nitraminofurazanate-based salts is favorable for further improving the density and detonation properties of its salt. The tetrazole-functionalized salts exhibit the best detonation properties among the three-salt series.

Energetic salts based on bis(*N*-dinitroethyl)aminofurazan were synthesized and characterized using NMR, IR, elemental analysis, density analysis, and DSC [1101]. These salts exhibited high densities (1.72 to 1.94 g/cm<sup>3</sup>) and low solubilities in water. Based on the experimental densities, the detonation pressures and velocities of the energetic salts were calculated, ranging from 26.1 to 39.4 GPa and 8055 to 9388 m/s, respectively. These values were higher than those of TNT and similar to those of RDX.

3,3'-Diamino-4,4'-azoxyfurazan (DAAF) along with 3,3'-azobis(6-amino-1,2,4,5-tetrazine) [DAAT] and 1,4-dihydrazino tetrazine (DHTz) were synthesized and characterized by IR, NMR, MS, TG-DTA, DSC, TG-FTIR, impact, and friction sensitivity tests [682]. DAAF is insensitive to mechanical stimuli whereas DAAT and DHTz are vulnerable to impact stimuli. The theoretical explosive power of DAAF, DAAT,

and DHTz alone and their combinations with well-known IHE as well as that of propellants based on them were calculated.

The thermal decomposition behaviors and thermal properties of diaminoazofurazan (DAAzF) and diaminoazoxyfurazan (DAAF) were studied by DSC with heating rates of 2.5, 5, 10, and 20 °C/min using TGA/DTG at a heating rate of 10 °C/min, VST, and thermal explosion tests [677]. The values of calculated activation energies of DAAzF and DAAF were 333.3 and 219.3 kJ/mol, with a natural logarithm of pre-exponential factors ( $\ln A$ ) of 67.535 and 49.230 s<sup>-1</sup>, respectively. Loss of weight during constant temperature at atmospheric pressure was 0.08% at 100 °C/48 h and 0.47% at 100 °C/48 h. The thermal explosion temperatures for five and 1000 s delay were 648 K (375 °C) and 552.6 K (279.5 °C) for DAAzF and 493 K (220 °C) and 495 K (222 °C) for DAAF, respectively. These results indicated that DAAzF and DAAF have good thermal stability and that the thermal stability of DAAzF is superior to that of DAAF. Sensitivity tests indicated that DAAzF and DAAF are insensitive to impact, friction, and electrostatic spark. Average particle size diameters of DAAzF and DAAF were less than 10 μm. Diaminofurazan, 3,4-diamino-1,2,5-oxadiazole, is a useful precursor for the preparation of new energetic materials, including 3,3'-dinitroamino-4,4'-azoxyfurazan. 3,3'-Dinitroamino-4,4'-azoxyfurazan has the highest calculated crystal density of 2.02 g/cm<sup>3</sup> at 173 K (the gas pycnometer measured density is

<sup>a</sup> Thermal decomposition temperature (onset) under nitrogen gas, DSC, 5 °C/min.

Data source: [1102].

1.96 g/cm<sup>3</sup> at 298 K) for any *N*-oxide energetic compounds yet reported [1102]. It forms salts with ammonium, hydrazinium, hydroxylammonium, or triaminoguanidinium cations, which by themselves are useful as energetic compounds, possibly even as replacements for AP in solid propellants. Table 73 is a summary of the properties of 3,3'-dinitroamino-4,4'-azoxyfurazan and some of its salts in comparison to RDX.

A theoretical study on the thermal decomposition mechanism of 3,3'-dinitro-4,4'-azoxyfurazan (DNAF) showed that *trans*-DNAF has a twisting configuration due to the substituted NO<sub>2</sub> on the furazan rings and the oxidation of azo-group [698]. The BDE of the two C—N bonds that connect the furazan rings and azo-group were found to be 275.7 and 385 kJ/mol (65.9 and 92 kcal/mol), respectively, suggesting that the C—N bond on the side of the O-atom of the azoxy-group is relatively weak.

Two high-nitrogen energetic compounds, 3-azido-5-guanidino-1,2,4-oxadiazole (AOG), containing 66.65% N, and 3,6-bis(3'-azido-1',2',4'-oxadiazole-5'-guanyl)-1,2,4,5-tetrazine (AOG2Tz), containing 67.62% N, were synthesized and characterized by DSC [1103]. AOG and AOG2Tz decomposed at 469 K = 196 °C and 483 K = 210 °C, respectively. They have a high density, favorable detonation properties, and a low sensitivity to impact.

For additional information on furazans as energetic materials see also [1]. That publication places particular focus on DAAzF and also on compounds containing linked furazan and tetrazine rings. Azido- and/or nitro-substituted furazans are even more energetic than aminofurazans [694]. Hydroxylammonium salts of furazans would be interesting as energetic materials and sources of nitrogen for gas generators [702].

Nitrogen-bridged furazan-based polyheterocyclic compounds were prepared and characterized by enthalpies of formation, thermal stability, and detonation properties [1104]. This included 3,6-bis(furazan-5-ylamino)-1,2,4,5-tetrazine (FSF), 3,4-bis(1,2,4,5-tetrazine-3-ylamino)-furazan (SFS), 3,4-bis(1*H*-1,2,3,4-tetrazole-5-ylamino)-furazan (TFT), and 1,5-bis(furazan-3-ylamino)-1*H*-1,2,3,4-tetrazole (FTF).

### 15.3 Furoxans

1-Oxa-2,5-diazol-2-oxide (furoxan) is the parent compound of another family of energetic materials. There may be some confusion as to which heteroatom on the oxadiazole ring the counting of positions starts on. We assume that the counting starts on the oxygen atom and that it goes counterclockwise.

Dinitrodiazenefuroxan, azoxynitrofuroxan,  $C_4N_8O_7$ , (DNAF) has received much attention because of its energy potential due to it being superior to that of HMX. However, a more detailed characterization of this compound is needed before it can be used [699, 1105]. It has a density of  $1.82 \text{ g/cm}^3$ , an oxygen balance of  $-5.9\%$ , and an enthalpy of formation of  $+154.7 \text{ kJ/mol}$ .

Dinitrodiazenefuroxan

4,4'-Dinitro-3,3'-diazonofuroxan, DDF,  $C_4N_8O_8$ ,  $M = 288.092 \text{ g/mol}$ , is a primary explosive. The two rings are connected by a  $-N=N-$  bridge with one oxygen atom outside of each furoxan ring.

4,4'-Dinitro-3,3'-diazonofuroxan

DDF has a positive enthalpy of formation of ( $\Delta H_f = +668 \text{ kJ/mol} = +159.6 \text{ kcal/mol}$ ). It has the highest detonation velocity of any known explosive at  $10 \text{ km/s}$  (measured experimentally) and a density that matches that of single crystals of  $2.02 \text{ g/cm}^3$ .

3-Nitro-5-guanidino-1,2,4-oxadiazole,  $C_3H_4N_6O_3$ , was synthesized from diaminoglycoluril with *in-situ* generated DMDO and used as an intermediate for the additional energetic materials with oxadiazole rings [663]. The impact sensitivity of 3-nitro-5-guanidino-1,2,4-oxadiazole was more than 40J (which is essentially insensitive). In the DSC, the decomposition temperature was 563 K (290 °C) whereas unsubstituted 1,2,4-oxadiazole became unstable at 361 K (88 °C). The density of 3-nitro-5-guanidino-1,2,4-oxadiazole is 1.766 g/cm<sup>3</sup>. It has an oxygen balance of -46.5% and an enthalpy of formation of +235.1 kJ/mol.

Attaching the furoxan ring to a benzene ring and loading the benzene ring up with nitro groups has led to a family of powerful benzofuroxan (phenylfuroxan) explosives, e.g., 3-nitro-4-(3,4,5-trinitrophenyl)furoxan [1106, 1107]. 4,6-Dinitrobenzofuroxan is an explosive that is less powerful than RDX [1108].

The thermal decomposition of 3,4-dinitrofurazanofuroxan (DNTF) under different pressure conditions and its reactions with catalysts were investigated by using DSC and TGA [1109]. The results showed that when the pressure increased, the endothermic fusion peak temperature of DNTF was almost constant, however, the major exothermic decomposition peak temperature at 2 MPa shifted to a higher temperature and the decomposition became more violent. Compared to the atmospheric reaction, the decomposition heat gain was obvious. The kinetic parameters of DNTF decomposition were obtained; the values of  $E_a$  and  $\ln A$  were 58.8 kJ/mol and 1.08 s<sup>-1</sup> for ambient pressure and 205.1 kJ/mol and 33.64 s<sup>-1</sup> for 2 MPa, respectively.

3,4-Dicyanofuroxan, 2-oxy-furazan-3,4-dicarbonitrile, (sometimes erroneously called 4,5-dicyanofuroxan), DCFO,  $C_4N_4O_2$ , CAS RN [17557-81-2],  $M = 136.068$  g/mol, has been evaluated as a gas generant for gas dynamic lasers but was eventually discarded due to safety reasons [1110].

3,4-Dicyanofuroxan

3,4-Dicyanofuroxan melts at 310–311 K (37–38 °C). A series of tests were made to determine the detonation propagation characteristics of 3,4-dicyanofuroxan. It was found that a detonation could be propagated through tubing as small as 2.5-mm (0.098-in.) internal diameter. Propagation was found to occur both in the solid state at ambient temperature and in the liquid state at 347 to 350 K (74 to 77 °C). A detonation sensitivity (a pseudo-card-gap) test was conducted and indicated that neat DCFO would be classified as a Class A explosive. More than 75 cards were required to prevent the detonation of neat DCFO; 70 cards or more designates a Class A explosive. A different

approach was to emphasize storable diluent compounds based on the substitution of carbon monoxide for a portion of the nitrogen in the GDL medium. This was aimed at alleviating problems associated with the fuel. Carbonyl diisocyanate, CDI,  $C_3O_3N_2$ , was characterized as a possible storable diluent and its combustion characteristics were determined in a small combustion facility.

3,4-Dicyanofuroxan is the starting product in the synthesis of 3,4-bis(1*H*-5-tetrazolyl)furoxan by converting the  $-CN$  groups to tetrazole rings by reaction with sodium azide.

3,4-bis(1*H*-5-tetrazolyl)furoxan

3,4-Bis(1*H*-5-tetrazolyl)furoxan (H2BTF) has two acidic hydrogen atoms and can form monoanionic or dianionic salts. Nine different salts of H2BTF with hydrazinium or triazolium and tetrazolium cations with varying degrees and types of substituents on the heterocyclic cation ring were synthesized and thoroughly characterized by multinuclear NMR and IR spectroscopy, DSC, gas density pycnometer, and elemental analyses [1111]. The densities of the energetic salts ranged between 1.63 and 1.79 g/cm<sup>3</sup>, as measured by a gas pycnometer. The hydrazinium salt of H2BTF has a calculated density of 1.820 g/cm<sup>3</sup>. Detonation pressures and detonation velocities were calculated to be 23.1–32.5 GPa and 7740–8790 m/s, respectively, and compared to the performance of RDX. Similar compounds with stronger bases were synthesized; both hydrogens of H2BTF were active in protonating nitrogen-rich bases during this process of forming dianionic salts [1112].

A series of energetic salts based on 4-nitro-3-(5-tetrazole)furoxan,  $C_3HN_7O_5$ , HTNF, have been synthesized and characterized by NMR, IR, elemental analysis, and DSC [1113].

4-Nitro-3-(5-tetrazole)furoxan (HTNF)

The crystal structures of neutral HTNF and its ammonium and *N*-carbamoylguanidinium salts have been determined by single-crystal XRD. The densities of these salts

were found to range from 1.63 to 1.84 g/cm<sup>3</sup>. Impact sensitivities have been determined by hammer tests and the results ranged from 2J (very sensitive) to >40J (insensitive). Theoretical performance calculations predicted detonation pressures and velocities in the ranges 25.5–36.2 GPa and 7934–8919 m/s, respectively, which make them competitive energetic materials in comparison to RDX.

### 15.4 Oxazoles

Because oxazole contains one oxygen atom in the ring and one less CH group, it would have a better oxygen balance compared to pyrrole. Oxazoles have an oxygen and a nitrogen separated by one carbon atom. The counting starts at the oxygen atom and not at the nitrogen atom.

Oxazoles are aromatic compounds but less so than thiazoles. Oxazole, 1,3-oxazole, C<sub>3</sub>H<sub>3</sub>ON, CAS RN [288-42-6], is a weak base; its conjugate acid has a pK<sub>a</sub> of 0.8 compared to 7 for imidazole. It has a boiling point of 342–343 K (69–70 °C) and a density of 1.050 g/cm<sup>3</sup>. Oxazolidine has both double, unsaturated bonds reduced to saturated bonds. If one adds a –CH<sub>2</sub>– group to the ring to make a symmetric molecule, one obtains morpholine. An entire book has been devoted to the chemistry of oxazoles: [1114]. Oximes serve as intermediates in the synthesis of oxaza heterocyclic compounds [1115].

Substituted oxazoles and oxazolidinium salts have been evaluated as energetic ingredients. 4,5-Dicyanooxazole, a low hydrogen content fuel, has been synthesized, characterized, and evaluated as a gas generant for gas dynamic lasers [1116]. Water (steam) in the exhaust attenuates the output of chemical lasers. Because of a need for a low hydrogen content fuel for use in gas dynamic lasers, 4,5-dicyano oxazole was prepared as a possible candidate for evaluation. Its physical properties were found to be well within desired limits for fuel requirements. However, difficulties inherent in the synthetic process made the production of the test or operational quantities excessively tedious and costly.

Quaternary methyl-alkyl-oxazolidinium salts with nitrate and perchlorate as the anion have been characterized as energetic compounds [202]. They melt below 373 K and are thermally stable at up to 523 K.

## 16 Pentazoles

Future sets of this encyclopedia of rocket propellants will contain a section on all-nitrogen and high-nitrogen compounds because pentazole and pentazole ions were studied in the hope of potential applications of such compounds in solid propellants and gas generants [1117]. Other hydronitrogens were described in this volume in the chapter on “Hydronitrogen Compounds.”

### 16.1 Theoretical Considerations About Pentazoles

While the existence of pentazole or hydrogen pentazole was once questioned [1118], the successful synthesis of the chain-like V-shaped  $N_5^+$  cation in 1999 by Christe and co-workers [1119] sparked renewed interest in all-nitrogen compounds, be they open-chained or ring-closed. Extensive theoretical and experimental work on the cyclic pentazole anion  $N_5^-$  resulted in its detection in the gas phase by mass spectroscopy in 2002 [1120, 1121].

The decomposition barrier for the cyclic  $N_5^-$  anion has been estimated to be 108.8 kJ/mol (26 kcal/mol) by using high-level *ab initio* calculations [1122], but the detection of the pentazole anion in the condensed phase by NMR spectroscopy has proven difficult. There are other pentazole compounds where the  $N_5$  ring has been stabilized by fused aromatic rings. It was hoped that the attachment of an oxygen atom to the pentazole ring would stabilize the molecule but that has not yet been confirmed. Quantum mechanical *ab initio* calculations gave a predicted enthalpy of formation of the ammonium pentazolate of +12.1 kJ/mol (+2.9 kcal/mol) and a density of 1.6 g/cm<sup>3</sup>.

The synthesis of the pentazole anion has been suggested and attempted using substituted aryl pentazoles as precursors. Future computational studies should be able to show if selective oxidation of aryl pentazoles is possible without destroying the  $N_5$  ring. The pentazole anion is expected to form strong ferrocene-like sandwich complexes in the presence of metal cations (e.g.,  $Fe_2^+$ ), which should favor its formation and stabilization in solution.

The structures of protonated pentazole cations ( $RN_5H^+$ ), oxygen-containing anions such as  $N(NO_2)_2^-$ ,  $NO_3^-$ , and  $ClO_4^-$ , and the corresponding ion pairs were investigated by *ab initio* quantum chemistry calculations [1123]. The stability of the pentazole cation was explored by examining the decomposition pathways of several mono-substituted cations ( $RN_5H^+$ ) to yield  $N_2$  and the corresponding azidinium cation. The HOFs of these cations were calculated based on isodesmic (bond-type conserving) reactions. The decomposition may involve a proton-transfer reaction from the cation to the anion.

The kinetic stability of dinitramide, trinitrogen dioxide, pentazole, and oxopentazole anions was evaluated in the gas phase and in solution by using high-level *ab*

*initio* and DFT calculations [1122]. Theoretical UV spectra, solid-state HOFs, density, as well as propellant performance for the corresponding ammonium salts were predicted. All calculated properties for dinitramide (the only stable anion of the four candidates known so far) were in excellent agreement with experimental data. Oxopentazolate is expected to be approximately 1200 times more stable than pentazolate in solution, with a barrier exceeding 30 kcal/mol, which should enable handling at room temperature. Based on calculation results, further study and attempted synthesis of these materials was deemed worthwhile [1124].

The possibility of the existence of cyclopentazan, which is a polynitrogen compound with a formula of  $N_5H_5$ , has been examined, including in comparison to the pentazolate anion, which is an all-nitrogen aromatic compound with a formula of  $N_5^-$  [1125]. The synthesis of various arylpentazoles was followed by oxidative or reductive ways, which led to the pentazolate anion. Polynitrogen-based compounds, triazanes, and azimines were then used in attempted cycloadditions, in the hope that this would lead to cyclopentazan. Complexing the polynitrogen-compound with various metal cations may result in more stable compounds.

## 16.2 Experimental Preparations of Pentazoles

The first successful synthesis of  $N_5^+$  cation was achieved in 1999 by Christe and co-workers, although it was an open-chain  $N_5$  and not the ring-shaped pentazole [1119].  $N_5^+$  salts can be made by reacting  $N_2F^+$  with hydrazoic acid to yield  $N_5^+ + HF$ , then reacting the  $N_5^+$  solution with  $AsF_6^-$  or  $SbF_6^-$  forms a stable  $N_5^+$  salt [1126]. The heavy  $SbF_6^-$  anion required to stabilize the labile  $N_5^+$  is not a good choice for rocket propellant. It is, however, interesting and novel chemistry nevertheless, and could lead to new potential rocket propellants.

# 17 Six-Membered Rings with One Nitrogen Atom

## 17.1 Pyridine

Coal tar was once a major source of raw materials for the organic chemical industry. Pyridine,  $C_5H_5N$ , CAS RN [110-86-1],  $M = 79.0999$  g/mol, was a common contaminant in benzene that was derived from coal tar.

Pyridine

Pyridine has a melting point of 232 K ( $-41^{\circ}\text{C}$ ), a boiling point of 388.5 K ( $115.4^{\circ}\text{C}$ ), a density of  $0.9780\text{ g/cm}^3$  at 298 K ( $25^{\circ}\text{C}$ ), and an enthalpy of formation of  $+99.96 \pm 0.50\text{ kJ/mol}$  ( $+23.89\text{ kcal/mol}$ ). Complete reduction of pyridine leads to hexahydropyridine, which is called piperidine. These compounds have been considered as fuels in hypergolic bipropellants. Their salts with oxidizing acids (nitric acid, perchloric acid) have been considered as additives in solid propellants and explosives.

Pyridine mixed with energetic hypergolizing agents was used successfully in combination with hydrogen peroxide, leading to very fast hypergolic ignition, with ignition delay times as short as 3 ms [1127].

### 17.1.1 Pyridinium Salts

Pyridinium salts with oxidizing acids (nitric acid, perchloric acid) have been considered as additives in solid propellants and explosives. Pyridinium perchlorate is not very soluble in water. For this reason, pyridinium perchlorates have been used to purify pyridine by recrystallization of the salt or to identify substituted pyridine bases by doing melting-point measurements. Occasional explosions have occurred when the salts were overheated or scraped during drying. Pyridinium perchlorate melts at 561 K ( $288^{\circ}\text{C}$ ), decomposes at 613 K ( $340^{\circ}\text{C}$ ) forming white fumes, and auto-ignites soon thereafter, burning with a sooty flame. Mixtures of pyridinium perchlorate and AP burn cleanly and rapidly. Pyridinium perchlorate is almost as powerful an explosive as TNT, with a lead block expansion of 95% of that of TNT, but is much more sensitive to impact (40% of that of picric acid).

Melting temperatures, glass transition temperatures, decomposition temperatures, heat capacities, and viscosities for a large series of pyridinium-based ionic liquids were measured. For comparison, data for several imidazolium and quaternary ammonium salts were included [1128]. Many of these compounds did not crystallize but formed glasses at temperatures between 188 and 223 K. Viscosities generally increased with increasing number and length of alkyl substituents on the cation, with the pyridinium salts typically being slightly more viscous than the equivalent imidazolium compounds.

Pyridinium or piperidinium nitrate or perchlorate were patented as additives to WFNA and were supposed to improve ignition with hydrocarbon fuels [1129]. Pyridinium nitrate is an ionic liquid. The thermal stability and decomposition kinetics of the ionic liquid pyridinium nitrate was investigated by non-isothermal TGA in an inert atmosphere (under nitrogen) [1130]. For the kinetic experiments, the thermal behavior of the sample was studied in the temperature interval from 360 up to 600 K at four different heating rates (5, 10, 15, and 20 K/min.). The kinetic parameters (activation energy and pre-exponential factor) of pyridinium nitrate decomposition under nitrogen atmosphere were evaluated by two model-free methods; the Friedman method and the Kissinger-Akahira-Sunose method. Depending on the calculation model used, the obtained activation energy and pre-exponential factor values (with respect to the degree

of sample conversion during the kinetic experiment for the method) ranged in the intervals of 76.36–112.56 kJ/mol and  $1.72 \times 10^5$ – $1.42 \times 10^{10}$  min.<sup>-1</sup>, respectively. Based on the kinetic parameters it was established that decomposition of pyridinium nitrate occurred as a first-order reaction. Some alkylpyridinium salts have also been identified as ionic liquids.

Perchlorate salts of pyridine, 2-chloropyridine, and 2-hydroxypyridine have been prepared and characterized by gravimetric TGA, DTA, and elemental analyses [1131]. Both substituted pyridinium salts were thermally less stable than the unsubstituted pyridinium perchlorate. Pyridinium perchlorate melted at 374 K (101°C), the 2-chloropyridinium perchlorate melted at 395 K (122°C), and the 2-hydroxypyridinium perchlorate melted at 366 K (93°C). Isothermal TGA gave the kinetics of thermal decomposition in the temperature range of 563–683 K (290–410°C) using both model fitting and isoconversional methods. The isoconversional method has been found to be superior to the conventional model-fitting method, and it was able to describe the decomposition process of these salts more accurately. Explosion delay measurements have been carried out to investigate the response of the salts under conditions of rapid heating. The thermolysis of pyridinium perchlorates involves a proton transfer from the pyridinium ion to the perchlorate anion as the rate-determining step.

### 17.1.2 Other Energetic Pyridinium Salts

The crystal structure of pyridinium dinitramide was examined and the question of oxygen coordination versus nitrogen coordination was clarified, also for the lithium dinitramide dihydrate [1132]. Pyridinium dinitramide had already been characterized in a separate study.

The reaction yield during the synthesis of pyridinium dinitramide (Py-DN) is 10% higher than that achieved with other dinitramide salts such as ammonium dinitramide (ADN). This is because Py-DN was directly converted without the sequential precipitation of intermediates [1133, 1134]. A thermal analyzer, a UV-visible spectrophotometer, and an FTIR spectrophotometer were used to characterize the physical and chemical properties of the synthesized Py-DN. The results were compared with previously prepared salts such as ADN and guanidinium dinitramide (GuDN). The characteristic endothermic and exothermic decomposition temperatures of Py-DN were 350.5 K (77.4°C) and 417.8 K (144.7°C), respectively, and the material had a heat of combustion caloric value of 1739 J/g. A low onset of exotherm can reduce the preheating temperature required for thruster operations.

### 17.1.3 Aminopyridines

Aminopyridines have properties similar to aniline and have been evaluated as ingredients in rocket propellants. The 2- and 4-aminopyridines form a mono-perchlorate salt with perchloric acid, whereas the 3-aminopyridine can even form a diperchlorate salt with an excess of acid [1135].

### 17.1.4 Nitropyridines

Unlike benzene, pyridine is resistant to direct nitration and more aggressive nitration methods, or other circuitous synthesis routes must be sought for making nitropyridines [1136]. The nitro group can go into the 2-, 3-, or 4-position in relation to the nitrogen atom in the ring. There are more compounds described in the literature that carry one or more additional substituent on the pyridine ring in addition to the nitro group. Nitropyridine-*N*-oxides are potential propellant ingredients.

### 17.1.5 Dinitropyridine and Trinitropyridine

A different method was found for the synthesis of 2,4,6-trinitropyridine and 2,6-diazido-4-nitropyridine [1137]. The substances were characterized by IR and DSC. 2,4,6-Trinitropyridine is thermally stable and comparable to trinitrobenzene (TNB) and its shock sensitivity is comparable to that of RDX. The explosive performance of 2,4,6-trinitropyridine and 2,6-diazido-4-nitropyridine was superior to that of TNT or TNB. Dinitropyridine and dinitropyridine derivatives with additional hydroxyl-, amino-, or *N*-oxide groups have been patented as insensitive explosives [1138]. A study of the formation of trinitropyridine-*N*-oxide from dinitroethanol and nitric acid pointed toward the possibility of making trinitropyridine, which cannot be obtained by direct nitration [1139, 1140]. The predicted detonation velocities for trinitropyridine-*N*-oxide and trinitropyridine were 8450 and 7880 m/s, respectively. 2,4,6-Trinitropyridine-1-oxide can be obtained from 2,2-dinitroethanol potassium salt and phosphoric acid along with 2,4,6-trinitropyridine as a byproduct [1141]. Treating 2,4,6-trinitropyridine-1-oxide in 2-N H<sub>2</sub>SO<sub>4</sub> with aqueous NaNO<sub>2</sub> produced more 2,4,6-trinitropyridine. 2,4,6-Trinitropyridine-1-oxide decomposed without melting while 2,4,6-trinitropyridine melted without decomposition.

Properties of polynitro-bridged pyridine derivatives were predicted by quantum mechanical MO computations [1142]. Gas-phase HOFs for the designed compounds were calculated using isodesmic reactions and their solid-phase HOFs were estimated using the Politzer approach. All designed compounds had large solid-phase HOFs, larger than 700 kJ/mol. Based on the predicted crystal densities, solid-phase HOFs, and chemical energies, detonation properties were then evaluated using K-J empirical equations. The results revealed that predicted detonation velocities and the pressures of all of the designed compounds should be above 9.3 km/s and 40 GPa, respectively. In addition, the lowest BDE indicated the weak points limiting their thermal stability. The impact sensitivity of polynitropyridines and similar polynitroheteroarenes and nitroheterocyclic compounds can be predicted by interpolating between known data and applying structural factors [148, 149].

### 17.1.6 Polyazidopyridines

The nitrogen content and energy content of pyridine can be increased by attaching azide groups. The most interesting energy characteristics were found for 2,4,6-triazido-

3,5-dicyanopyridine, which considerably surpasses 2,4,6-triazido-1,3,5-triazine in the enthalpy of formation (+5740 kJ/kg) but is much less explosive [1143].

### 17.1.7 Pyridine-N-Oxides

Explosives with low sensitivity and high energy containing pyridine rings were sought. The nitramine group with N—NO<sub>2</sub> bonds was introduced into this effort as much as possible [1144]. Based on research into the regular relationship between molecular structures, crystal structures, and explosive properties as well as safety of performance, the molecular structures of several target compounds and their synthetic methods were designed. Then synthetic routes were outlined with different synthetic reactions such as condensation, *N*-nitration, *N*-oxidation, and *C*-nitration.

2,6-Diamino-3,5-dinitropyridine-1-oxide and aminonitropyrimidine-1,2-dioxides were prepared and showed stability and insensitivity comparable to that of TATB, which has a legendary good thermal stability [1145]. Although the stability of the new compounds was good, the explosive performance lagged behind the established goal. In trying to create chemical structures similar to TATB, 3,5-dinitro-2,4,6-triaminopyridine was prepared by oxidative amination of 2-chloro-3,5-dinitropyridine or 2,6-diamino-3,5-dinitropyridine or by treatment of this with hydroxylamine [1146]. 3,5-Dinitro-2,4,6-triaminopyridine-1-oxide was prepared by oxidation of the parent heterocycle with hydrogen peroxide, or by treatment of 2,6-diamino-3,5-dinitropyridine-1-oxide with hydroxylamine. The intra-molecular and intermolecular hydrogen bonding contributes to the thermal stability and low impact sensitivity of these molecules.

2,6-Dinitro-3,5-diaminopyridine-*N*-oxide, DADNPO, CAS RN [181766-17-6], C<sub>5</sub>H<sub>5</sub>N<sub>5</sub>O<sub>5</sub>, *M* = 215.13 g/mol, is a structural isomer to 2,6-diamino-3,5-dinitropyridine-1-oxide and is commercially available from EURENCO [1147]. DADNPO is a new explosive that can tolerate temperatures about 40 °C higher than HNS, and with the same degree of degradation. This explosive can therefore be used in hotter bore holes than HNS shaped charges for oil well completion, with equal performance. The detonation velocity is approximately 7000 m/s, the friction sensitivity is >350 N, and the impact sensitivity is >19 J.

## 17.2 Piperidine and Piperidine Derivatives

### 17.2.1 Piperidine

Piperidine, also known as hexahydropyridine, pentamethyleneimine, C<sub>5</sub>H<sub>11</sub>N, CAS RN [110-89-4], with a molecular mass of 85.1475 g/mol, is a cyclohexane in which one CH<sub>2</sub> group has been replaced by an NH group. It is a ring-closed secondary amine. It can be made via the reduction of pyridine. The application of piperidine and alkyl-substituted piperidines as hypergolic rocket fuels has been patented for compounds with the general formula (CH<sub>2</sub>)<sub>5</sub>NR, where R is an alkyl group [1148].

Piperidine, hexahydropyridine, pentamethyleneimine,  $C_5H_{11}N$ , is the parent compound of a series of energetic materials. Piperidine itself is a secondary amine with a freezing point of 264 K ( $-9^\circ\text{C}$ ), a boiling point of 379 K ( $106^\circ\text{C}$ ), and a density of  $0.8606\text{ g/cm}^3$ .

(3,3,5,5-Tetranitropiperidin-1-yl)acetic acid is a precursor for the synthesis of 1,3,3,5,5-pentanitropiperidine,  $C_5H_6N_6O_{10}$ , CAS RN [71706-07-5],  $M = 310.135\text{ g/mol}$ .

1,3,3,5,5-Pentanitropiperidine

Treatment of 2,2-dinitropropane-1,3-diol with glycine in water at 338–343 K ( $65\text{--}70^\circ\text{C}$ ) for 5 h gave (3,3,5,5-tetranitropiperidin-1-yl)acetic acid. Exhaustive nitration of the latter in a mixture of 100% nitric acid and trifluoroacetic anhydride for 12 h gave 1,3,3,5,5-pentanitropiperidine [1149]. (3,3,5,5-Tetranitropiperidin-1-yl)acetic acid and 1,3,3,5,5-pentanitropiperidine were characterized by IR, NMR, DSC, and elemental analysis. 1,3,3,5,5-Pentanitropiperidine has a melting point of 393–398 K ( $120\text{--}125^\circ\text{C}$ ) and a density of  $1.82\text{ g/cm}^3$ .

2,2,6,6-Tetramethyl-1-oxopiperidinium perchlorate has been synthesized and the IR, UV, and NMR spectra have been recorded [1150]. An XRD structural study of 2,2,6,6-tetramethyl-oxopiperidinium perchlorate  $[C_5H_6(CH_3)_4NO]^+ClO_4^-$  has been carried out, with results as follows: space group  $P2_12_12_1$ ,  $a = 14.01$ ,  $b = 11.045$ ,  $c = 8.139\text{ \AA}$ , and  $Z = 4$ . The structure was determined by the heavy-atom method and refined by the method of least squares. According to the IR spectra, the crystals have a twisted “bathtub” conformation with an angle twist of  $24^\circ 30'$ . The melting point of the crystals was 430–431 K ( $157\text{--}158^\circ\text{C}$ ).

Polynitropiperidines would make good rocket propellants and explosives. *N*-Nitroalkyl-3,3,5,5-tetranitropiperidines can be prepared by condensation of 2,2,4,4-tetranitropentane-1,5-diol with a dinitroalkylamine such as  $H_3CC(NO_2)_2(CH_2)_nNH_2$  [1151]. Examples are *N*-2,2,2-trinitroethyl-3,3,5,5-tetranitropiperidine,  $C_7H_8N_8O_{14}$ , with a melting point of 436–441 K ( $163\text{--}168^\circ\text{C}$ ), and *N*-3,3,3-trinitropropyl-3,3,5,5-tetranitropiperidine,  $C_8H_{10}N_8O_{14}$ , with a melting point of 415–417 K ( $142\text{--}144^\circ\text{C}$ ). 1,3,3,5,5-Pentanitropiperidine,  $C_5H_6N_6O_{10}$ ,  $M = 310.14\text{ g/mol}$ , can be prepared by nitration of 3,3,5,5-tetranitropiperidine with concentrated nitric acid [1152]. It melts at 393–398 K ( $120\text{--}125^\circ\text{C}$ ) and has a density of  $1.82\text{ g/cm}^3$  and a heat of combustion

of 2056 cal/g. Its Trauzl lead block indentation was 165% of that of TNT. Its impact sensitivity was 35–40 cm with a 2-kg mass. 3,3,5,5-tetranitropiperidine,  $C_5H_7N_5O_8$ , with a melting point of 396–400 K (123–127 °C) can be prepared by reaction of 2,2,4,4,-tetranitropentane-1,5-diol with ammonium acetate [1153].

### 17.2.2 Piperidinium Salts

Piperidine forms salts with strong acids. Piperidinium nitrate and piperidinium perchlorate, along with a long list of alkyl- and arylammonium nitrates, have been claimed as propellant ingredients, typically as monopropellants in nitric acid solution that are similar to CAVEA [1154, 1155], or as additives in JP-4, which helps the ignition of kerosene fuels in a ramjet [1156]. This latter patent claims piperidinium nitrate, pyridinium nitrate, or 2-methylpyridinium nitrate as fuel additives. The piperidinium or pyridinium nitrates or perchlorates can also be dissolved in  $HNO_3$ ,  $H_2O_2$ , or  $RNO_2$  solvents to make more energetic monopropellants [1157].

Piperidinium nitrate was studied by FTIR and FT-Raman spectroscopy in the range of 100–4000  $cm^{-1}$  at 300 K, and FTIR spectra were recorded down to 90 K [1158]. DSC measurements exhibited two phase transitions at 256 and 295 K.

Piperidine was chosen as a reference compound for DFT calculations to predict the HOFs for seven  $C-NF_2$  or  $C-NO_2$  substituted heterocyclic ring compounds via designed isodesmic reactions [1159]. Similar to the behavior of many other amines, piperidine forms solid Lewis adducts with diborane and other boranes that are hypergolic with nitric acid and can be used as fuel grains in hybrid rockets [1160].

## 17.3 Morpholine and Morpholine Derivatives

### 17.3.1 Morpholine

Morpholine, also known as 1,4-oxazinane, tetrahydro-1,4-oxazine, tetrahydrop-oxazine,  $O(CH_2CH_2)_2NH$ ,  $C_4H_9NO$ , CAS RN [110-91-8], is a heterocyclic amine and a base that can form salts with strong acids. Because it already contains some oxygen, it is not useful as a fuel. It is mostly used for pH adjustment in boiler feedwater treatments to reduce corrosion in steam plants. Morpholine mixed with energetic hypergolizing agents was used as rocket fuel in combination with hydrogen peroxide [1127].

Morpholine forms salts with strong acids. Morpholinium dinitramide melts at 355–357 K (82–84 °C) [1161]. The enthalpy of formation of morpholinium dinitramide is –226 kJ/mol (–54 kcal/mol) [1161].

### 17.3.2 Morpholine Derivatives

The counting in heterocyclic rings containing O and N as heteroatoms starts at the O atom, not at the N atom. The energy content of morpholine can be improved by ni-

trating the N—H in the ring with a nitrating mixture consisting of fuming nitric acid and acetic anhydride, forming a nitramine. An example is *N*-nitromorpholine, 4-nitromorpholine,  $C_4H_8N_2O_3$ , with a molecular mass of 132.1179 g/mol [1162].

A patent [1163] claims the application of alkyl-substituted morpholines as hypergolic rocket fuels. The patent covers compounds with the general formula  $O(CR_2)_4NR$ , where R can be a hydrogen or a lower alkyl group

Alkylmorpholine

### 17.3.3 Other Oxazine Derivatives

Two geminal azido nitro compounds, 5-azido-3-*tert*-butyl-5-nitrotetrahydro-2*H*-1,3-oxazine and 5-azido-3,5-dinitrotetrahydro-2*H*-1,3-oxazine (AZDNOX), were synthesized and characterized [1164]. The first compound and its dinitro analog, 3-*tert*-butyl-5,5-dinitrotetrahydro-2*H*-1,3-oxazine, have been obtained in good yields by the reactions of 5-nitrotetrahydro-2*H*-1,3-oxazine salts with azide and nitrite ions in the presence of potassium ferricyanide. Combustion behaviors of AZDNOX and 3,5,5-trinitrotetrahydro-2*H*-1,3-oxazine (TNOX), have been studied. Burning rate measurements have been performed in a constant-pressure bomb in the pressure range of 0.1–15 MPa and temperature profiles in the combustion wave of AZDNOX and TNOX were measured using thin tungsten-rhenium thermocouples.

## 18 Six-Membered Rings with Two Nitrogen Atoms

If two nitrogen atoms are introduced into the benzene ring, they can occupy three different positions: the 1,2 vicinal position: pyridazine; the 1,3 unsymmetrical position: pyrimidine; and the 1,4 symmetric position: pyrazine. All three diazine isomers and their hydrogenated relatives are stable and form the nucleus of numerous compounds of interest as energetic materials and pharmaceuticals.

Pyridazine   Hexahydropyridazine   Pyrimidine   Hexahydropyrimidine   Pyrazine   Piperazine

## 18.1 Pyridazine

Pyridazine, also known as 1,2-diazine,  $C_4H_4N_2$ , CAS RN [289-80-5], is a colorless liquid with a freezing point of 265 K ( $-8^\circ\text{C}$ ) and a boiling point of 481 K ( $208^\circ\text{C}$ ). The density is  $1.107\text{ g/cm}^3$ . It is a strong base and forms salts with many acids. Several books have been devoted to the chemistry of pyridazines [1165, 1166]. The latter volume substantially updated the original pyridazines volume which was first published in 1973.

### 18.1.1 Pyridazinium Salts

Pyridazinium monoperchlorate,  $(C_4H_4N_2)HClO_4$ , undergoes structure and phase transitions with changing temperature. This has been characterized by XRD, dielectric, and optical measurements [1167–1169]. At room temperature the crystal is monoclinic, space group  $P2_1/n$ . Anomalous behavior is characteristic of first-order phase transitions at 343 and 339 K on heating and cooling, respectively.

Quaternary pyridazinium salts with varying lengths alkyl group and terminal fluorine substitution in the alkyl group with nitrate or perchlorate as the anion had low melting points 289–331 K ( $16$ – $58^\circ\text{C}$ ), making them ionic liquids with good thermal stability [202].

### 18.1.2 Tetrahydropyridazine and Hexahydropyridazine

Hexahydropyridazine is a cyclic hydrazine but is rarely used in its pure state. Most work is done on hexahydropyridazine derivatives but they do not seem to be suitable as rocket propellants. Tetrahydropyridazine can be prepared by oxidation of 1-aminopyrrolidine. Hexahydropyridazine can be prepared by reduction of tetrahydropyridazine [1170, 1171]. Another process for making hexahydropyridazine runs via catalytic cyclization and alcoholysis using diformylhydrazine and 1,2-dichlorobutane or 1,2-dibromobutane as starting reagents [1172].

## 18.2 Pyrimidine

Pyrimidine, 1,3-diazine,  $C_4H_4N_2$ , CAS RN [289-95-2], forms low-melting colorless crystals that melt at room temperature from between 293–295 K ( $20$ – $22^\circ\text{C}$ ) and boil at 397 K ( $124^\circ\text{C}$ ). It is soluble in water and forms salts with strong acids such as nitric acid or perchloric acid. Alicyclic imines with two nitrogen atoms may be derived from imidazolidine or hexahydropyrimidine. These amines are potentially useful hypergolic fuels. The theoretical performance of 1,3-dimethylimidazolidine and its homologue 1,3-dimethylhexahydropyrimidine as hypergolic fuels was predicted from computational chemistry calculations [1173]. An entire book has been devoted to the chemistry of pyrimidines [1174].

2,4,6-Triazido-5-(azidomethyl)-pyrimidine (TAAMP)

In search of potential ionic liquids, it was found that one or more additional azidomethyl groups dramatically decreased the melting points of the corresponding azidopyrimidines [1175, 1176]. 2,4,6-triazido-5-(azidomethyl)-pyrimidine,  $C_5H_2N_{14}$ , has a nitrogen content of 75.96 mass-%, a HOF of 1452.7 kJ/mol, melts at 295.6 K (22.5 °C), decomposes at 466 K (193 °C), and has a density of 1.65 g/cm<sup>3</sup>. Theoretical calculations showed that these polyazido compounds are very energetic. In this family of compounds, 3,6-di(azido)-tetrazine has the highest reported HOF of ~1101 kJ/mol (6709 kJ/kg). It melts and decomposes at 403 K (130 °C) and has a density of 1.72 g/cm<sup>3</sup>. 2,4,6-Triazidotriazine has a HOF of 1050 kJ/mol, melts at 367 K (94 °C), decomposes at 453 K (180 °C), and has a density of 1.72 g/cm<sup>3</sup>. The compound 4,4',6,6'-tetra(azido)azo-1,3,5-triazine has a HOF of 2171 kJ/mol (6164 kJ/kg). 2,4,6-Triazidopyrimidine was found to be a precursor to carbon nano-tubes in the presence of  $Ni(ClO_4)_2$ . Thermal decomposition of some of these compounds gave nitrogen-rich nano-layered, nano-clustered, and nano-dendritic carbon nitrides, depending on the different heating processes.

5-Nitropyrimidine is often used as an intermediate for the synthesis of chemicals that may be used as pharmaceutical drugs or herbicides. The impact sensitivity of polynitropyrimidines and similar polynitroheteroarenes and nitroheterocyclic compounds can be predicted by interpolating between known data and applying structural adjustment factors [148, 149].

### 18.2.1 Pyrimidinium Salts

Protonation or alkylation of pyrimidine typically takes place at only one of the ring nitrogen atoms.

### 18.2.2 Hexahydropyrimidine

Hexahydropyrimidine is the fully reduced form of pyrimidine. It is a ring-closed secondary amine. Several books have been devoted to the chemistry of pyrimidines and several sections in the books on pyrimidines deal with the reduced pyrimidines: [1177, 1178]. 1,3,5,5-Tetranitrohexahydropyrimidine is a thermally stable, high-melting ener-

getic compound. It can be prepared by nitration of 1,3-diisopropyl-5,5-dinitrohexahdropyrimidine with 90%  $\text{HNO}_3$ .

Triple aminoalkylation of nitromethane with formaldehyde and *tert*-butylamine resulted in a cyclic Mannich base, the nitrolysis of which gave 1,3,5-trinitro-hexahdropyrimidine (TNP) [1179]. Two of the nitro groups are on a nitrogen atom, thus making this a nitramine, and one of the nitro groups is attached to a carbon atom. Hydroxymethylation and subsequent nitration converted it to 5-nitroxymethyl-1,3,5-trinitrohexahdropyrimidine. Both compounds exhibited explosive properties.

The kinetics and mechanism of the thermal decomposition of 1,3,5-trinitrohexahdropyrimidine (TNP), morphology, and the gaseous products evolved were analyzed using TGA, DTA, DSC, IR, XRD, and hot-stage microscopy [1180]. The elementary cell parameters obtained from the XRD pattern were:  $a = 18.818 \pm 0.005 \text{ \AA}$ ,  $b = 18.818 \pm 0.005 \text{ \AA}$ , and  $c = 4.867 \pm 0.005 \text{ \AA}$ . Kinetic rate parameters were evaluated from the induction period as well as from isothermal TGA. The activation energy of TNP decomposition was 202.05 kJ/mol, and the pre-exponential factor  $\log A$  (in units of  $\text{s}^{-1}$ ) was 22.78 based on results from TGA measurements. Slightly different data,  $E_{\text{act}} = 181.133 \text{ kJ/mol}$  and  $\log A = 20.97 \text{ s}^{-1}$  were obtained from IR measurements. The cleavage of the N—N bond appears to be the primary step in the thermolysis of TNP.

1,3,5,5-Tetranitrohexahdropyrimidine, also known as DNNC,  $\text{C}_4\text{H}_6\text{N}_6\text{O}_8$ , CAS RN [81360-42-1],  $M = 266.126 \text{ g/mol}$ , was synthesized from 2,2-dinitro-1,3-propanediol by a cyclization reaction with *tert*-butylamine and formaldehyde followed by nitration. This replaced the *tert*-butyl groups with nitro groups. DNNC has been evaluated as an oxidizer and as a replacement for AP [1181].

DNNC has a density of  $\rho = 1.82 \text{ g/cm}^3$ , an enthalpy of formation of +46 kJ/mol (+11 kcal/mol), and a melting point of 424–427 K (151–154 °C). The impact sensitivity in an Allegany Ballistics Laboratory (ABL) tester was 3.5 cm and the friction sensitivity in the ABL friction sensitivity tester was 660 lbf at 8 ft/s.

### 18.3 Pyrazines

Pyrazine,  $C_4H_4N_2$ , 1,4-diazine, 1,4-diazabenzene, p-diazine, CAS RN [290-37-9], forms low-melting colorless crystals with a density of  $1.031 \text{ g/cm}^3$  that melt at 326 K ( $53^\circ\text{C}$ ) and boil at 388 K ( $115^\circ\text{C}$ ). It is soluble in water and forms salts with strong acids such as nitric acid or perchloric acid. A comprehensive review of the entire chemistry of pyrazines is published in [1182].

#### 18.3.1 Tetra-Substituted Pyrazine Derivatives

2,6-Diamino-3,5-dinitropyrazine is a precursor for making 2,6-diamino-3,5-dinitropyrazine-1-oxide, which has been investigated as an IHE. 2,6-Diamino-3,5-dinitropyrazine, 3,5-dinitro-2,6-pyrazinediamine; 2,6-pyrazinediamine, 3,5-dinitro-;  $C_4H_4N_6O_4$ , DADNPZ; CAS RN [52173-59-8],  $M = 200.11 \text{ g/mol}$ , melts at 573–623 K ( $300\text{--}350^\circ\text{C}$ ) (dec.), has a density of  $1.860 \text{ g/cm}^3$ , and a HOF of  $-22.6 \text{ kJ/mol}$  ( $-5.4 \text{ kcal/mol} = -27 \text{ cal/g}$ ).

#### 18.3.2 2,6-Diamino-3,5-dinitropyrazine-1-oxide

2,6-Diamino-3,5-dinitropyrazine-1-oxide, also known as LLM-105, ANPZ-O,  $C_4H_4N_6O_5$ , CAS RN [194486-77-6],  $M = 216.11 \text{ g/mol}$ , melts at 575 K ( $302^\circ\text{C}$ ) (dec.), has a density of  $1.913 \text{ g/cm}^3$ , and an enthalpy of formation of  $-13.0 \text{ kJ/mol}$  ( $-3.1 \text{ kcal/mol} = -14 \text{ cal/g}$ ). 2,6-Diamino-3,5-dinitropyrazine-1-oxide is an *N*-oxide and is an IHE.

2,6-Diamino-3,5-dinitropyrazine-1-oxide (LLM-105)

2,6-Diamino-3,5-dinitropyrazine-1-oxide, which was developed at the Lawrence Livermore National Laboratory, is also referred to as LLM-105 [227, 1183–1185]. Its structure is related to that of 2,6-dinitro-3,5-diaminopyridine-*N*-oxide. It is thermally stable, has a density of  $\rho = 1.913 \text{ g/cm}^3$ , a melting point of  $348^\circ\text{C}$  (dec.), and a detonation velocity of 8730 m/s. LLM-105 has performance and insensitivity properties between those of HMX and TATB. Its calculated energy content is about 81% that of HMX but 15% more than that of TATB and 30% more than that of TNT. DSC traces (exotherm onset 627 K =  $354^\circ\text{C}$ ) indicated that it is thermally more stable than most known high explosives and is nearly identical to TATB. It is insensitive to shock, spark, and friction and its impact insensitivity (drophammer results) ( $DH_{50} = 117 \text{ cm}$ ) approaches that of TATB ( $DH_{50} > 177 \text{ cm}$ ),

however, it is less sensitive than RDX. The impact sensitivity is dependent on particle morphologies. Coarse particles (80  $\mu\text{m}$ ) had a DH50 of 115–120 cm but smaller (rapidly precipitated or ball-milled) powder was more sensitive and had DH<sub>50</sub> values in the 55–80 cm range. In the crystal lattice, these IHE pack in either graphite-like sheets (TATB and DAAF) or a herringbone arrangement (FOX-7 and LLM-105). This maximizes the amount of  $\pi$  stacking between each molecule, which enhances stability.

There are various methods to prepare compound LLM-105, with most methods starting from commercially available 2,6-dichloropyrazine and oxidizing 2,6-diamino-3,5-dinitropyrazine in the final step to the 1-oxide [1186, 1187]. Other synthesis methods start with 2,6-diaminopyrazine-1-oxide (DAPO) [1188, 1189]. DAPO can be made by the nitrosation of iminodiacetonitrile to *N*-nitroso biscyanomethylamine and via the formation of DAPO via condensation of hydroxylamine with *N*-nitroso biscyanomethylamine.

The thermal and shock sensitivities of PBX formations based on 2,6-diamino-3,5-dinitropyrazine-1-oxide (commonly called LLM-105, which stands for Lawrence Livermore Molecule #105) were investigated using a one-dimensional time to explosion (ODTX) apparatus to generate times to thermal explosion at various initial temperatures [1190]. A four-reaction chemical decomposition model was developed to calculate the time to thermal explosion versus reciprocal absolute temperature curve. LLM-105 exhibited thermal and shock sensitivities intermediate between those of TATB and HMX.

LLM-105 has performance that is superior to TATB and TATB-like insensitivity. A recrystallization study on LLM-105 included the use of an ionic liquid solvent to aid in dissolution [1191]. The use of ionic liquids in recrystallizing highly insoluble energetic materials is a new technique. The recrystallization study evaluated alternative methods to achieve the desired particle size, purity, and morphology of LLM-105.

The enthalpies of formation for 2,6-diamino-3,5-dinitropyrazine (**I**), 2,6-diamino-3,5-dinitropyrazine-1-oxide (**II**) (LLM-105), and 2,6-diamino-3,5-dinitropyrazine-1,4-dioxide (**III**) were calculated using quantum mechanical computational methods to obtain accurate energies. These were compared with experimental values that were available for (**I**) and (**II**) [1192]. 2,6-Diamino-3,5-dinitropyrazine (**I**) was theoretically identified as the most stable compound, both thermodynamically (least endothermic) and with respect to its impact sensitivity. The gas phase enthalpy of formation was predicted as +126.8 kJ/mol (+30.3 kcal/mol). The enthalpy of sublimation was predicted as 108.4 kJ/mol (25.9 kcal/mol). This leads to an enthalpy of formation for the solid of +18.4 kJ/mol (+4.4 kcal/mol), which was in fair agreement with the experimental value of –13.0 kJ/mol (–3.1 kcal/mol). Based on their calculations, LLM-105 has a high density of 1.92 g/cm<sup>3</sup>, a detonation velocity of 8516 m/s (literature: 8730 m/s), and a detonation pressure of 320 kbar (literature 359 kbar), which are comparable to those of RDX. However, LLM-105 is much less impact sensitive than RDX and is not sensitive towards electrostatics and friction. 2,6-Diamino-3,5-dinitropyrazine 1,4-dioxide (**III**) was identified as a promising nitrogen-rich explosive that exceeded

the explosive power of **(II)**. Its performance is comparable, or slightly superior, to that of RDX.

LLM-105 can be prepared by methoxylation, nitration, amination, and oxidation using 2,6-dichloropyrazine as the starting material. The effects of the methoxylation reaction condition, different nitration systems, different amination systems, and the volume ratio of trifluoroacetic acid and hydrogen peroxide on the total yield of LLM-105 were investigated [1193, 1194]. Optimized synthesis conditions were: 25% sodium methoxide methanol solution; reflux for 3 h; 2,6-dimethoxypyrazine as intermediate for nitration; 20% oleum and potassium nitrate nitration system; the reaction at room temperature for 3 h; protonic solvent ethanol as amination solvent; the reaction at 333 K (60 °C) for 2 h; the volume ratio of trifluoroacetic acid and 30% hydrogen peroxide as 3:2; the reaction at 318 K (45 °C) for 6 h. The total yield of LLM-105 was 54%.

2,6-Diaminopyrazine, as the precursor of LLM-105, was synthesized via cyclization with *N*-nitrosobis(cyanomethyl) amine as the starting material. Following that, LLM-105 was synthesized via three different routes: nitration and *N*-oxidation for the first route, *N*-oxidation and nitration for the second route, and finally, acetylation, *N*-oxidation, and nitration for the third route [1195]. Through the comparisons of the reaction conditions of nitration and *N*-oxidation and the total yield and purity of the target product of the three different routes, it was found that the route with acetylation, *N*-oxidation, and nitration (with a yield of LLM-105 of 45.8% and purity over 99%) was the best choice. Detonation velocity, detonation pressure, DSC, and sensitivities of impact for LLM-105 were measured and the results showed that the capabilities of LLM-105 are greater than that of TATB. The structures of the intermediates and LLM-105 were characterized by <sup>1</sup>H-NMR, IR, and MS spectra. An improved synthesis method for 2,6-diamino-3,5-dinitropyrazine-1-oxide (LLM-105) gave a total yield of 54% [1196].

2,6-Diamino-3,5-dinitropyrazine-1-oxide (LLM-105) was synthesized by methoxylation, nitration, amination, and oxidation using 2,6-dichloropyrazine as starting material, with an overall yield of 60.2% [1197]. LLM-105 and its intermediates were characterized by IR, <sup>1</sup>H NMR, MS, and elemental analysis. The structure of LLM-105 was computed using a B3LYP quantum mechanical method. A study of the relationship between the steady geometric configuration and the temperature of thermodynamic properties showed that all atoms of the pyrazine ring are mainly coplanar, and that the values of heat capacity and entropy increase with increasing temperature (over the temperature range of 273 to 1000 K).

The nitration reaction process for the synthesis of 2,6-diamino-3,5-dinitropyrazine was investigated using 2,6-dimethoxypyrazine as raw material under different nitration conditions, including mixed acid, oleum-nitric acid, and oleum-KNO<sub>3</sub> [1198]. The effect of the mixed acid ratio, reaction time, and reaction temperature on the yield of the nitration reaction product were explored. The optimal process conditions of the nitration were determined as follows: reaction temperature 298 K (25 °C), reaction time 3 h, 20% oleum-KNO<sub>3</sub> system (molar ratio 3.5:1) in which KNO<sub>3</sub> is in excess of 100%, and a 0.1 mol dosage of 2,6-dimethoxypyrazine. Under these conditions, the yield of 2,6-dimethoxy-3,5-dinitropyrazine was 67.8%.

As already discussed earlier, gas-phase enthalpies of formation for NTO, DADNE, LLM-105, TNT, RDX, TATB, HMX, and PETN were calculated using quantum composite methods [488]. Calculations for HMX and PETN dealt with the largest molecules attempted with these methods at any time before. Some calculations were close to one another, with a larger difference found between other methods used. The mean absolute deviations between average experimental values and calculations were 12 to 3 kcal/mol.

While the mono-*N*-oxide of 2,6-diamino-3,5-dinitropyrazine can be prepared by a variety of different methods and has been described in detail, the di-*N*-oxide, 2,6-diamino-3,5-dinitropyrazine-1,4-dioxide, is more difficult to obtain. Very little has been published about this more energetic (that is, more energetic than LLM-105) compound. One of the synthesis methods starts with pyrazine-2,3-dicarboxylic acid and goes through a series of nitration, amination, and oxidation steps [1199].

### 18.3.3 Pyrazinium Salts

Pyrazine is less basic than pyridine, pyridazine, or pyrimidine. The acidity constant ( $pK_a$ ) is 0.37. It forms salts with strong acids. Quaternary pyrazinium salts with varying lengths of alkyl group and terminal fluorine substitution in the alkyl group with perchlorate as the anion had low melting points of 345–375 K (72–102°C) and good thermal stability [202].

## 18.4 Piperazine

The completely reduced pyrazine is piperazine, a dual secondary amine, also known as  $\text{HN}(\text{CH}_2\text{CH}_2)_2\text{NH}$ ,  $\text{C}_4\text{H}_{10}\text{N}_2$ , 1,4-diazane, 1,4-diazacyclohexane, hexahydropyrazine, piperazidine, diethylenediamine, CAS RN [110-85-0]. Piperazine is a symmetric molecule with the base properties of a double secondary amine.

Piperazine

One of its derivatives, 1,4-dimethylpiperazine, a tertiary diamine that is dissolved in gasoline, kerosene, JP-4, isooctane, or cyclohexane, has been patented as a hypergolic rocket fuel [1200]. Piperazine is a white crystalline solid with a melting point of 379 K (106°C), a boiling point of 419 K (146°C), and demonstrates complete miscibility with water. A form in which piperazine is commonly available industrially is as the hexahydrate,  $\text{C}_4\text{H}_{10}\text{N}_2 \cdot 6\text{H}_2\text{O}$ , which melts at 317 K (44°C) and boils at 398–403 K (125–130°C).

Its acidity ( $\text{pK}_a$ ) is 9.8 and it forms monoprotinated and diprotinated salts with strong acids. Many modern notable drugs contain a piperazine ring as part of their molecular structure.

#### 18.4.1 Piperazinium Salts

Piperazine can form mononitrate and dinitrate (PIPDN) salts. The thermal decomposition of piperazinium(2+) dinitrate was examined by DSC and rapid-scan FTIR [1201]. The decomposition of PIPDN initially yields  $\text{HNO}_3$  but then generates a significant amount of *N,N*-dinitrosopiperazine along with small molecule fragments. The presence of nitrosamines strongly increases the health hazard of the materials upon heating. No nitramines were detected as thermolysis products. The crystal structure of PIPDN was determined during the same effort.

Piperazinium(2+) dinitrate and piperazinium(2+) diperchlorate have been examined as potential propellant ingredients. Piperazinium(2+) dinitrate, 1,4-diazacyclohexane dinitrate,  $[\text{H}_2\text{N}(\text{C}_2\text{H}_2)_2\text{NH}_2](\text{NO}_3)_2$ , melts at 468 K (195 °C) and, in the DTA, the two maxima of two exotherm peaks are at 540 and 577 K (267 and 304 °C) [1202].

Piperazinium(2+) diperchlorate crystallizes as  $[\text{H}_2\text{N}(\text{C}_2\text{H}_2)_2\text{NH}_2](\text{ClO}_4)_2 \cdot 2\text{H}_2\text{O}$ , the dihydrate. The IR spectrum of the compound exhibited characteristic absorptions at  $1100\text{ cm}^{-1}(\text{s})$ ,  $970\text{ cm}^{-1}(\text{m})$ , and  $620\text{ cm}^{-1}(\text{s})$ . This is due to the Cl—O stretching vibrations of  $\text{ClO}_4$  with  $T_d$  symmetry. The broad absorption band at  $3480\text{ cm}^{-1}$  and a medium intensity band at  $1630\text{ cm}^{-1}$  are the characteristics of lattice water. The absorption frequencies at  $3180\text{ cm}^{-1}(\text{s})$  and  $1595\text{ cm}^{-1}(\text{s})$  are attributed to the  $-\text{NH}_2$  groups of the piperazinium cation.

The thermal stability of piperazinium(2+) diperchlorate dihydrate was measured by simultaneous TGA and DTA in an argon atmosphere at a heating rate of 2/min [1203]. From the TGA, one can see that the compound loses weight in two stages. The first stage registers a loss of 9.5%, which occurs in the temperature range of 328–443 K (55–170 °C). The weight loss observed was attributed to the dehydration process as it corresponded to the calculated weight loss of 11% for the removal of two molecules of water of hydration from the parent compound. There was an endothermic peak around 348 K (75 °C) in the DTA curve. The anhydrous material was found to be stable up to 513 K (240 °C). In the second stage, between 513 and 553 K (240 and 280 °C), the compound decomposed with a mild explosion, and the reaction was highly exothermic. No residue was left behind at 553 K (280 °C). The DTA displayed a sharp exothermic peak at 563 K (280 °C). The mass spectrum was extremely complex and showed masses that were attributed to two linked diazane rings.

Piperazinium(2+) bis-dinitramide melts at 485–487 K (212–214 °C) [1161]. The enthalpy of formation of piperazinium(2+) bis-dinitramide was not measured but was extrapolated from similar compounds with known properties and was concluded to be  $-236\text{ kJ/mol}$  (calc.) ( $-56.4\text{ kcal/mol}$ ) [1161].

*N,N,N',N'*-Tetraaminopiperazinium is a quaternary dianionic cation that can form salts with many energetic anions, including an 5,5'-azotetrazolate [1204, 1205].

N,N,N',N'-Tetraaminopiperazinium Dication

#### 18.4.2 Piperazine Derivatives

Instead of having two loose alkyl groups dangling from the sides of the  $-\text{N}(\text{NO}_2)-$  group, the secondary amine from which a nitramine is derived could be a heterocyclic amine where the ring contains two or more  $-\text{CH}_2-$  or  $-\text{NH}-$  or  $-\text{O}-$  groups. Piperazine derivatives of particular interest are the nitramine and the dinitramine in which one or both hydrogens on the nitrogen(s) are replaced by nitro groups, thus forming cyclic nitramines.

1,4-Dinitropiperazine, 1,4-dinitro-1,4-diazacyclohexane,  $\text{C}_4\text{H}_8\text{N}_4\text{O}_4$ , CAS RN [4164-37-8], DNPP, 1,4-DNDC,  $M = 176.13 \text{ g/mol}$ , is a cyclic nitramine that is similar to RDX, except that it contains only two instead of three nitramino  $>\text{N}-\text{NO}_2$  links in the ring.

1,4-Dinitropiperazine, DNPP

1,4-Dinitropiperazine melts at 490 K and the heat of fusion is  $33.29 \text{ kJ/mol}$  [1206]. The standard enthalpy of formation of solid DNPP is  $+53 \pm 2 \text{ kJ/mol}$  ( $+12.7 \pm 0.4 \text{ kcal/mol}$ ) and the enthalpy of sublimation of DNPP is  $111 \pm 0.8 \text{ kJ/mol}$  ( $26.6 \pm 0.2 \text{ kcal/mol}$ ). The heat of combustion of DNPP is  $2669 \pm 1.7 \text{ kJ/mol}$  ( $638 \pm 0.4 \text{ kcal/mol}$ ) [1207].

The synthesis of 1,4-dinitro-2,3-dinitraminopiperazine was achieved by a circuitous route, starting with a Mannich reaction of ethylenediamine, glyoxal, and urea to form 2,5,7,9-tetraazabicyclo[4.3.0]nonan-8-one, which was nitrosated to give 2,5-nitroso-2,5,7,9-tetraazabicyclo[4.3.0]nonan-8-one, then nitrated to give 2,5,7,9-tetranitro-2,5,7,9-tetraazabicyclo[4.3.0]nonan-8-one. This was then hydrolyzed to give 1,4-dinitro-2,3-dinitraminopiperazine, which is a highly energetic compound [1208].

Attaching two azidoethyl groups to the nitrogens in the 1,4-positions of piperazine makes a more energetic molecule, 1,4-bis-(2-azidoethyl)-piperazine. The double chloride salt has a formula of  $\text{C}_8\text{H}_{18}\text{N}_8\text{Cl}_2$  which has been described in a publication [1209]. It crystallized in monoclinic shapes, space group  $P2_1/n$  (No. 14), with crystal lattice parameters of  $a = 6.5246(3) \text{ \AA}$ ,  $b = 7.7090(4) \text{ \AA}$ ,  $c = 13.9243(6) \text{ \AA}$ ,  $\beta = 101.240(3)^\circ$ ,  $V = 686.93(6) \text{ \AA}^3$ , and  $Z = 2$ .

## 19 Triazines

Triazines are six-membered aromatic heterocycles that contain three nitrogen atoms in a symmetrical arrangement (*s*-triazines = 1,3,5-triazines) or unsymmetrical (= 1,2,3- or 1,2,4 triazines) arrangement:

1,2,3-Triazine

1,2,4-Triazine

1,3,5-Triazine

Two comprehensive reviews of the entire chemistry of triazines have been published [1210, 1211]. Many energetic compounds are based on triazine [1212].

The thermal decomposition mechanism of *s*-tetrazine was studied by combining the *ab initio* molecular dynamics (AIMD) method and the DFT method [1213]. The dissociation channel was first simulated in several trajectories based on an AIMD method, then further examined using Gaussian 98 to locate the minimum points and the transition structure. High-accuracy single-point calculations were performed and the rate constants were calculated by a microcanonical variational transition state theory. The studies suggested that *s*-tetrazine undergoes concerted triple dissociation to form one N<sub>2</sub> and two HCN.

### 19.1 Hexahydrotriazine

Hexahydrotriazine, 1,3,5-triazacyclohexane, 1,3,5-triazinane, C<sub>3</sub>H<sub>9</sub>N<sub>3</sub>, CAS RN [110-90-7], is a cyclic trifunctional secondary amine.

Hexahydrotriazine, 1,3,5-triazacyclohexane

Hexahydrotriazine forms salts with many acids. The mononitrate salt melts at 445–448 K (172–175 °C). In the DTA, the maximum exothermic peak is at 486 K (213 °C) [1202].

## 19.2 Mono-Substituted Triazines

Unlike other heterocyclic rings such as tetrazines and tetrazoles, the s-triazine ring is quite stable. It tends to undergo depolymerization before catastrophic decomposition. When the more energetic explosophoric groups are attached, the resulting materials have good thermal stability and high energy content.

## 19.3 Di-Substituted Triazines

### 19.3.1 Di-Substituted Hexahydrotriazines

1,3,5-Hexahydrotriazine is a ring-closed secondary amine. Substituents can be carried on either the carbon and/or the nitrogen atoms. 2-Nitroimino-5-nitro-hexahydro-1,3,5-triazine (NNHT) has been tested as a less sensitive explosive [1214].

2-Nitroimino-5-nitro-hexahydro-1,3,5-triazine (NNHT)

The thermal behavior and decomposition reaction kinetics of 2-nitroimino-5-nitro-hexahydro-1,3,5-triazine were investigated by TGA-DTA and DSC under atmospheric pressure and flowing nitrogen gas conditions [1215]. The results showed that the thermal decomposition process of NNHT has two mass loss stages. The kinetic parameters of the exothermic decomposition reaction mechanism were  $E_a = 132 \text{ kJ/mol}$  and  $\log(A) = 12.56 \text{ s}^{-1}$ , respectively. The kinetic equation can be expressed as:

$$\frac{d\alpha}{dt} = 10^{12.86} (1 - \alpha)^{\frac{3}{2}} \exp(-1.5849 \times 10^4 / T).$$

The critical temperature of thermal explosion of NNHT obtained from the peak temperature ( $T_p$ ) is  $T_{bp} = 467 \text{ K}$ . The drop weight sensitivity was compared to the thermal sensitivity of the material. A different kinetic rate equation describing the thermal decomposition reaction of NNHT was obtained by TGA-DTA and an integral isoconversional non-linear method [1216]. The standard molar heat capacity of NNHT was  $218 \text{ J mol}^{-1} \text{ K}^{-1}$  at  $298 \text{ K}$ .

The thermal properties and the decomposition mechanism of NNHT were studied by DSC-TGA-IR-MS methods [1217]. The results showed that two steps, the hexahydric ring framework cracking and the nitroamino group  $[\text{N}-\text{NO}_2]$  breaking initiate the major exothermic decomposition process. The gaseous products were  $\text{H}_2\text{O}$ ,  $\text{N}_2$ ,  $\text{CO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{HCHO}$ ,  $\text{NH}_3$ ,  $\text{CH}_2$ ,  $\text{NH}_2$ ,  $\text{CHO}$ ,  $\text{HCN}$ ,  $\text{HNCO}$ , and  $\text{NO}_2$ .

## 19.4 Tri-Substituted Triazines

The high symmetry of *s*-triazine derivatives imparts outstanding thermal stability to these molecules. A primary example is melamine dinnerware made from melamine-formaldehyde polymers. The same thermal stability is also imparted to explosives derived from triazines such as RDX. The behavior of triazines with substituents on the C-atoms (2,4,6-substituted) is quite different from molecules with substituents on the N-atoms (1,3,5-substituted).

### 19.4.1 1,3,5-Trinitro-1,3,5-hexahydrotriazine (RDX)

Concerning the energetic materials, the most famous *N*-substituted triazine is 1,3,5-trinitrotriazine, RDX, which is a cyclic nitramine. Trying to find the correct location to place the information on RDX in this book at hand depended on deciding whether to list it under nitramines (along with open-chain linear nitramines) in *Encyclopedia of Liquid Fuels*, chapter “Nitramines,” or to list it here under heterocyclic compounds with triazines. Once the decision was made about moving RDX to chapter “Nitramines,” HMX had to be moved as well to the section on eight-membered ring heterocyclic nitramine compounds.

#### 19.4.1.1 RDX Derivatives

Substituting some or all the hydrogens in the hexahydrotriazine ring with more energetic groups will result in energetic materials that have improved properties.

One of the more energetic derivatives, where three of the hydrogens in RDX have been replaced with trifluoromethyl groups, is 1,3,5-trinitro-2,4,6-tris(trifluoromethyl)-hexahydrotriazine (TTFMRDX).

#### 2,4,6-Trinitro-1,3,5-triazine

Electrophilic nitration of 1,3,5-triazine should lead to nitrotriazines with nitro groups on the C-atom instead of the N-atom. However, in contrast to the nitration of aromatic compounds, that of heteroaromatic compounds containing several nitrogen atoms is significantly inhibited due to the acceptor effect of the nitrogen atoms present in the ring (the nitration rate decreases 10<sup>6</sup>-fold upon substitution of one C=N for a C=C fragment). Nitration in acidic media creates additional difficulties due to easier protonation of nitrogen-containing heterocycles in comparison to aromatic rings, which also reduces the nitration rate. In general, direct nitration of six-membered azines is possible only if the heterocycle contains some activating groups (e.g., amino or hydroxy groups) or if it has *N*-oxide groups to start with. However, no more than two nitro groups can be incorporated simultaneously, irrespective of the nature of the heterocycle. An excellent overview of the chemistry of nitro-1,3,5-triazines is provided in [1218].

A few dimethylamino-substituted mononitro-1,3,5-triazines were prepared by photochemical oxidation of azido-1,3,5-triazines in the presence of oxygen or

by ozonization of the corresponding hydroxyaminotriazines or nitrosotriazines. A hypothetical route to 2,4,6-trinitro-1,3,5-triazine would be the trimerization of nitrocyanogen. While nitrotriazines were elusive, nitraminotriazines and nitromethyl-, and dinitromethyl- and trinitromethyltriazines were produced. Nitration of melamine gives dinitroammeline in 44–52% yield. 2,4,6-Tris-(trinitromethyl)-1,3,5-triazine was very difficult to synthesize [1219].

2,4,6-Trinitro-1,3,5-triazine, cyanuric trinitrate, is closely related to hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX), except that the nitro groups are not on the nitrogens as in nitramines, but they are attached to the carbon atoms of the triazine ring.

2,4,6-Trinitro-1,3,5-triazine

RDX

2,4,6-Trinitro-1,3,5-triazine would be a desirable high-energy material to have but all efforts to synthesize it so far have been unsuccessful. Nucleophilic nitration of cyanuric chloride with silver nitrite was the first, albeit unsuccessful, attempt to synthesize 2,4,6-trinitro-1,3,5-triazine. Several theoretical studies exploring the molecular structure, predicted enthalpy of formation, and performance as an explosive have been conducted [1220]. The standard enthalpy of formation  $\Delta H_f$  was calculated and found to be equal to  $+192 \text{ kJ/mol} = +46 \text{ kcal/mol}$  and the predicted density was  $2.1 \text{ g/cm}^3$ . Both values are higher than those of RDX [1221, 1222].

The molecular structures of all possible mono-, di-, and tri-nitro-substituted triazine compounds have been considered as potential candidates for HEDMs by using a quantum chemical treatment [1223]. Geometric and electronic structures, thermodynamic properties, and detonation performances of these nitro-substituted triazines were systematically studied using a DFT method. Predicted thermal stabilities were evaluated from the homolytic BDE. The results of the calculations indicated that mono-, di-, and tri-nitro-substituted derivatives of symmetric 1,3,5-triazine were expected to be more stable than their 1,2,3 and 1,2,4 counterparts.

The condensed phase theoretical enthalpy of formation, density, and explosive performance of six triazine derivatives with varying amounts of nitro groups and dinitrotriazolyl groups on the triazine ring were computed [1224]. The compounds hypothesized included 2-[3,5-dinitro-1,2,4-triazolyl(1)]-1,3,5-triazine, 2-[3,5-dinitro-1,2,4-triazolyl(1)]-6-nitro-1,3,5-triazine, 2-[3,5-dinitro-1,2,4-triazolyl(1)]-4,6-dinitro-1,3,5-triazine, 2,4-bis[3,5-dinitro-1,2,4-triazolyl(1)]-1,3,5-triazine, 2,4,6-tris[3,5-dinitro-1,2,4-triazolyl(1)]-1,3,5-triazine, and 2,4,6-trinitro-1,3,5-triazine.

### 19.4.2 2,4,6-Triamino-s-triazine (Melamine)

Melamine, 1,3,5-triazine-2,4,6-triamine, 2,4,6-triamino-s-triazine,  $C_3H_6N_6$ , CAS RN [108-78-1],  $M = 126.12$  g/mol, is a thermally very stable heterocyclic amine. Formally, it can be considered as a trimer of cyanamide  $N\equiv C-NH_2$ . Melamine can be produced by the pyrolysis of urea or guanidinium carbonate and by many other methods.

The kinetics of the potassium hydroxide-catalyzed formation of melamine from dicyandiamide in diethylene glycol monoethyl ether at 383–423 K (110–150 °C) is consistent with the rate of depolymerization of dicyandiamide to cyanamide [1225]. The rate of formation of melamine from a mixture of dicyandiamide and cyanamide (1 : 1 in molar ratio) was almost identical to that from cyanamide alone. These results suggested a mechanism involving rate-determining depolymerization of dicyandiamide to cyanamide followed by the condensation of the cyanamide produced with dicyandiamide, leading to melamine by cyclization.

The reaction of melamine with formaldehyde produces melamine resins, which are thermally stable and very durable thermosetting polymers used for many household items.

1,3,5-Triazine-2,4,6-triamine

An excellent summary of the preparation and properties of melamine and melamine derivatives has been compiled. This publication is a good starting point for further study [1226].

#### 19.4.2.1 Properties of Melamine

Melamine is a white solid with a very high melting point (with decomposition) of 618 K (345 °C) and a density of 1.574 g/cm<sup>3</sup>. It is slightly soluble in water (3.240 g/L at 293 K [20 °C]).

Melamine crystallizes in monoclinic crystals, space group  $P2_1/a$ , with  $a = 10.537(2)$  Å,  $b = 7.477(1)$  Å,  $c = 7.275(1)$  Å,  $\beta = 112^\circ 9'$ , and  $Z = 4$  [1227–1229]. The enthalpy of formation of melamine is  $-87.07$  kJ/mol ( $-20.81$  kcal/mol =  $-165$  cal/g) and the density is 1.573 g/cm<sup>3</sup> [61].

The pyrolysis of melamine has been studied within the temperature range 473–773 K (200–500 °C) [1230, 1231]. The results indicated three stages of decomposition with the loss of one, two, and three molecules of ammonia per two molecules of melamine corresponding to the formation of melam, melem, and melon, respectively. High-pressure pyrolysis of melamine leads to carbon nanotubes.

Trihydrazinotriazine,  $C_3H_9N_9$ , is also called triaminomelamine,  $N,N',N''$ -triaminomelamine,  $M=171.17$  g/mol. It is a good source of nitrogen for solid gas generators (73.65% N) [1232]. The enthalpy of formation of trihydrazinotriazine is +393.9 kJ/mol (+94.14 kcal/mol = +550 cal/g) and its density is 1.63 g/cm<sup>3</sup> [61]. Trihydrazinotriazine crystals are monoclinic, space group *Cc*, with unit cell parameters of  $a = 3.625$  Å,  $b = 17.603$  Å,  $c = 11.026$  Å,  $\beta = 101.9^\circ$ , and  $Z = 4$  [1233].

### 19.4.3 Melaminium Salts

#### 19.4.3.1 Melaminium Nitrate

Melamine forms a dinitrate salt with nitric acid, but only with an excess of acid [1135]. The gross formula is  $C_3H_8N_8O_6$ , CAS RN [10308-79-9]. Melaminium(2+) dinitrate melts at 477 K (204 °C). In the DTA, the maximum exotherm peak is 610 K (337 °C), making it thermally the most stable salt from a group of 15 heterocyclic compounds investigated [1202]. Melaminium(2+) dinitrate has been patented as an explosive for use in oil and gas exploration where high-temperature stability is required [1234].

Two energetic salts of the melaminium(1+) cation were prepared and characterized by XRD [1235]. The first was melaminium dinitramide, which crystallized in triclinic crystals, space group  $P\bar{1}$ , with  $a = 6.6861(11)$  Å,  $b = 6.9638(16)$  Å,  $c = 10.447(2)$  Å,  $\alpha = 99.07(3)^\circ$ ,  $\beta = 98.30(3)^\circ$ ,  $\gamma = 108.50(3)^\circ$ ,  $V = 445.6(2)$  Å<sup>3</sup>,  $Z = 2$ , and  $\rho = 1.74$  g/cm<sup>3</sup>. Melaminium nitrate crystallized in monoclinic crystals, space group  $P2_1/c$ ,  $a = 3.5789(7)$  Å,  $b = 20.466(4)$  Å,  $c = 10.060(2)$  Å,  $\beta = 94.01(2)^\circ$ ,  $V = 735.0(3)$  Å<sup>3</sup>,  $Z = 4$ , and  $\rho = 1.71$  g/cm<sup>3</sup>. The crystal structures of both salts showed distinct monoprotonated melaminium cations and dinitramide- or nitrate anions, respectively. Efficient packing in the solid state is achieved by extensive hydrogen bonding between two-dimensional zigzag ribbons of the melaminium cations and the respective anions, resulting in high densities of the solid-state structures.

The Raman and FTIR spectra of melaminium(1+) nitrate and its deuterated analogue were recorded in the solid phase [1236]. Molecular geometry and vibrational frequency values of melaminium(1+) nitrate in the electronic ground state were calculated using a DFT method. The calculated results showed that the optimized geometry can well reproduce the crystal structure, and the theoretical vibrational frequency values showed good agreement with experimental values. Melaminium nitrate (in proper dilution to make it non-explosive) is also used as a slow-release fertilizer.

#### 19.4.3.2 Melaminium Perchlorate

Melamine forms mono- and di-protonated salts with strong acids such as perchloric acid. Both melaminium(1+) perchlorate and melaminium(2+) diperchlorate have been made and characterized. They usually crystallize as hydrates with one or several molecules of water in the hydrate sphere (layer). They are potentially explosive.

Melaminium(2+) diperchlorate hydrate, melamine perchlorate, 2,4,6-triamino-1,3,5-triazine-diiium diperchlorate hydrate,  $C_3H_8N_6^{2+} \cdot 2ClO_4^- \cdot H_2O$ , has a high density

( $\rho = 1.94 \text{ g/cm}^3$ ) and its crystal structure is extensively hydrogen bonded and contains water dimers [1237]. Melaminium(2+) diperchlorate hydrate was among a group of melaminium salts prepared and characterized as prospective materials for non-linear optical applications and polarizability. The first and second hyperpolarizability was calculated [1238].

The constituents in 2,4,6-triamino-1,3,5-triazinium(1+) perchlorate monohydrate,  $\text{C}_3\text{H}_7\text{N}_6^+ \cdot \text{ClO}_4^- \cdot \text{H}_2\text{O}$ , are linked via hydrogen bonds of the  $\text{O}-\text{H}\cdots\text{O}$ ,  $\text{N}-\text{H}\cdots\text{O}$ ,  $\text{N}-\text{H}\cdots\text{N}$ , and  $\text{N}-\text{H}\cdots\text{Cl}$  types [1239]. All the H atoms of the melaminium cation are involved in the hydrogen bonds. The melaminium residues are interconnected by four  $\text{N}-\text{H}\cdots\text{N}$  hydrogen bonds. The ribbons are interconnected by other hydrogen bonds as well as by  $[\pi]-[\pi]$  interactions [centroid-centroid distance =  $3.8097 \text{ \AA}$ ]. The crystals are triclinic, space group  $P\bar{1}$ ;  $a = 5.654(4) \text{ \AA}$ ;  $b = 7.553(7) \text{ \AA}$ ;  $c = 11.893(10) \text{ \AA}$ ;  $\alpha = 102.72(4)^\circ$ ;  $\beta = 94.58(3)^\circ$ ;  $\gamma = 110.78(2)^\circ$ ;  $V = 456.1(7) \text{ \AA}^3$ ;  $Z = 2$ ;  $D_{\text{X-ray}} = 1.781 \text{ g/cm}^3$ ; m.p.  $> 470 \text{ K}$ .

Powder XRD analysis confirmed that melaminium(1+) perchlorate monohydrate crystals belong to the triclinic system with space group  $P\bar{1}$  [1240]. FTIR and FT-Raman spectra and  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were recorded at room temperature. Functional group assignment has been made for the melaminium cations and perchlorate anions. Vibrational spectra absorption bands were predicted using quantum chemical DFT calculations and were compared to experimental values.

Single crystals of melaminium perchlorate monohydrate were grown from aqueous solution by slow solvent evaporation at room temperature and used for structural and thermal analysis [1241]. X-ray powder diffraction analysis confirmed that melaminium perchlorate monohydrate crystallizes in the triclinic (space group  $P\bar{1}$ ) structure and the calculated lattice parameters were  $a = 5.6275 \pm 0.0780 \text{ \AA}$ ,  $b = 7.6926 \pm 0.1025 \text{ \AA}$ ,  $c = 12.0878 \pm 0.2756 \text{ \AA}$ ,  $\alpha = 103.89 \pm 1.01^\circ$ ,  $\beta = 94.61 \pm 0.92^\circ$ ,  $\gamma = 110.22 \pm 0.81^\circ$ , and  $V = 468.95 \text{ \AA}^3$ . The thermal decomposition behavior of melaminium perchlorate monohydrate was studied by TGA at three different heating rates of 5, 10, and  $20^\circ\text{C/min}$ . The decomposition of melaminium perchlorate monohydrate occurred in three stages, which included dehydration and decomposition. Dehydration took place between 373 and 393 K ( $100$  and  $120^\circ\text{C}$ ). A rapid mass loss of  $\sim 57\%$  occurred during the second stage between 573 and 623 K ( $300$ – $350^\circ\text{C}$ ). This was due to the elimination of melaminium cations. The thermal decomposition of melamine proceeded in stages and was accompanied by the detachment of ammonia. Melamine first decomposed into melam and then melon. The values of the effective activation energy ( $E_a$ ) and the pre-exponential factor ( $\ln A$ ) of each stage of thermal decomposition for all heating rates were calculated using three different methods. A significant variation of  $E_a$  with conversion ( $\alpha$ ) indicated that the process is kinetically complex.

Melaminium(1+) perchlorate has been patented as a propellant in mixtures with NC [1242]. Melaminium(1+) perchlorate has a melting point of 568 K ( $295^\circ\text{C}$ ) and is stable to 573 K ( $300^\circ\text{C}$ ).

### 19.4.3.3 Melaminium Nitroformate

Melaminium nitroformate (MNF) is a very stable nitroformate salt with interesting properties and qualifies as a potential propellant ingredient. It was thermally more stable than some of the other nitroformate salts investigated in the same study. Although two and three-fold protonated melaminium salts are known, the reaction between melamine and nitroform only afforded a 1:1 adduct [1243]. While studying the formation of melaminium salts, however, several single-crystal X-ray structures can be obtained. Two different modifications of MNF have been determined: a high-density modification with a density of  $1.914\text{ g/cm}^3$  and a low-density modification with a density of  $1.771\text{ g/cm}^3$ . The high-density modification of MNF crystallized in the space group  $P2_1/n$  (No. 14) with four formula units per unit cell, whereas the low-density modification crystallized in the chiral space group  $P2_1$  (no. 4) with two independent formula units per unit cell. Depending on the solvent from which MNF was crystallized, two distinctly different structures of MNF could be obtained on recrystallizing MNF from either dimethylsulfoxide or methanol. MNF melts at 391 K (118 °C) and starts to decompose at 416 K (143 °C). IR, Raman, and NMR spectra of the various polymorphs have been determined. The calculated enthalpy of formation for the high-density form is  $-15.48\text{ kJ/mol}$  ( $-3.7\text{ kcal/mol}$ ) and the predicted velocity of detonation is  $8693\text{ m/s}$ .

### 19.4.3.4 Other Melaminium Salts

Thermal decomposition and the non-isothermal kinetics of the thermal decomposition of melaminium 3-nitro-1,2,4-triazol-5-one salt (MNTO) were studied under non-isothermal conditions using DSC and TGA [1244]. The kinetic parameters were obtained from the analysis of the DSC and TGA curves using Kissinger and Ozawa methods. The critical temperature of thermal explosion ( $T_b$ ) was 574 K. The results showed that MNTO is thermally more stable than NTO when compared in terms of the critical temperature of thermal explosion.

### 19.4.4 Cyanuric Triazide

Cyanuric triazide, also known as 2,4,6-triazido-1,3,5-triazine, TAT,  $\text{C}_3\text{N}_{12}$ , CAS RN [5637-83-2],  $M = 204.113\text{ g/mol}$ , is a unique compound in that it consists of only carbon and nitrogen. Cyanuric triazide can be prepared by slowly introducing powdered cyanogen chloride into an aqueous solution of sodium azide with efficient cooling. Cyanuric triazide is extremely sensitive to impact and friction (0.1 N pistil load) and is an effective initiating primary explosive [1245], however, it is not used in practice due to its high vapor pressure. It forms colorless crystals melting with incipient decomposition at 367 K (94 °C = 201 °F). It is a good high-nitrogen compound containing 82.36 mass-% N.

2,4,6-Triazido-1,3,5-triazine (TAT)

The enthalpy of formation is  $+916 \text{ kJ/mol} = +4489.2 \text{ kJ/kg} = +219 \text{ kcal/mol} = +1072.9 \text{ kcal/kg}$ . In the lead block test, the bulging of the cavity was  $415 \text{ cm}^3/10 \text{ g}$ . The drop weight impact sensitivity of TAT is not much different from that of lead azide but it has not been used as a percussion cap stab-sensitive initiator. The drop weight sensitivity of cyanuric triazide was compared to that of other organic azides [1246].

Pulsed laser photolysis of cyanuric triazide resulted in all-nitrogen cations, which were detectable by MS spectrometry [1247]. Fragment peaks may be composed only of nitrogen atoms (atomic mass is 14) but the peak at mass 70 was strong. The fragment of mass 70 ( $14 \times 5$ ) was identified as  $\text{N}_5^+$ , which is considered to have covalent bonds. XRD studies of cyanuric triazide indicated the hexagonal prism-shaped crystals to be of space group  $C6_3/m$  [1248].

The infrared and Raman spectra of cyanuric triazide were obtained using pure crystalline samples and  $\text{CH}_2\text{Cl}_2$  solutions [1249]. Twenty-three of the 26 vibrational fundamentals and several combination bands could be assigned.

The azide-tetrazole isomerism in several polyazido-1,3,5-triazines, triazido-sym-heptazine, and some diazido-1,2,4,5-tetrazines was investigated by *ab initio* quantum chemical methods to determine whether the polyazides are suitable starting materials for the synthesis of the isomeric tetrazoles [1250]. In the gas phase, polyazidoheterocycles do not cyclize to form tetrazoles. An electron-donating amino group favors the ring closure to tetrazoles, whereas an electron-withdrawing nitro group favors the linear azides. Solvation in polar solvents favors the formation of a tetrazole ring system due to higher charge separation in the tetrazole ring system. However, for all polyazido-1,3,5-triazines, including triazido-s-heptazine, the effects of solvation are not strong enough to shift the equilibrium to the tetrazole side, which explains why several attempts to detect these compounds have failed. Diazidoazo- and hydrazotetrazines will readily cyclize to the tetrazoles in polar solvents.

A nitrogen-rich  $\text{C}_3\text{N}_{12}$  solid was predicted through a transformation from a molecular precursor, cyanuric triazide ( $\text{C}_3\text{N}_3)(\text{N}_3)_3$ , under extremely high pressure and temperature [1251]. The transformation mechanism is mainly governed by azide-tetrazole chain-ring tautomerism leading to the  $\text{sp}^2$  to  $\text{sp}^3$  orbital activation of all carbon atoms. The phase diagram and the equation of state were calculated together with the ambient metastability of the new  $\text{C}_3\text{N}_{12}$  solid, which had a material density of  $2.926 \text{ g/cm}^3$  and an energy density of  $15.56 \text{ kJ/g}$ .

Cyanuric triazide was compressed in a diamond anvil cell at pressures up to 63 GPa [1252]. Infrared spectra indicated the high-pressure formation of a lattice built of trietrazole molecular units.

#### 19.4.5 Other Tri-Substituted Triazines

2,2'-Diamino-4,4'-diazidoazotriazine, AMAZT,  $C_6H_4N_{16}$ ,  $M = 300.21$  g/mol, has been evaluated as a burning rate modifier. DFT calculations of the proton transfer in the gas phase and solvent effects on the structural transformation for a series of nitrogen-rich energetic salts derived from nitroamino-1,3,5-triazine predicted that proton transfer from the cations to anions within the salts in the gas-phase may result in neutral hydrogen-bonding complexes [1253]. These salts may be stabilized as ionic structures in the liquid state with solvation energies in the range of  $-37.72$  to  $+69.37$  kJ/mol. These ionic salts exhibited relatively high densities in the range of  $1.63$ – $1.96$  g/cm<sup>3</sup>. A combination of adding  $NH_3OH^+$  to the cation and the addition of a  $-NO_2$  or  $-NF_2$  group to the nitraminotriazine ring anion can improve the detonation performance. Most of the ammonium, hydroxylammonium, and hydrazinium salts were promising energetic materials. Several triazidotriazine derivatives are of interest as propellant ingredients or explosives.

Triazidotriazine Derivatives

The crystal morphologies, thermal behavior, sensitivity, and performance of 2-amino-4,6-diazido-*s*-triazine and its derivatives have been investigated using SEM, DSC, and TGA [1254]. The crystal morphologies of 4,6-diazido-*N*-nitro-1,3,5-triazine-2-amine (DANT), DAAT, 4,4',6,6'-tetraazido-hydrazo-1,3,5-triazine (TAHT), 4,4',6,6'-tetraazido-azo-1,3,5-triazine bis(4,6-diazido-1,3,5-triazin-2-yl)diazene (TAAT), and 2,4,6-trinitrophenyl-4,6-diazido-1,3,5-triazinyl-2-amine (TANDAzT) crystals depend on the conditions of crystallization and determine their sensitivity. The TGA/DSC thermal analysis indicated that there was only one step for the decomposition of

DAAT, while at least three steps were observed for the other materials. DAAT started to decompose at around 421 K (148 °C) with a peak temperature of 470 K (197 °C), while TAHT started to decompose at 440 K (167 °C) with shoulder-peak near 466–480 K (193–207 °C). DANT decomposed with a heat release of ~2500 J/g, which is much higher than that of DAAT thus indicating that the heat of decomposition and its release rate is greatly enhanced by the transformation of an amino to a nitroamino group. The thermal stability of TANDazT was slightly worse than that of DAAT, and it decomposed in the liquid state with a melting point of about 444 K (171 °C).

4,4',6,6'-Tetra(azido)azo-1,3,5-triazine,  $C_6N_{20}$ , 79.54% N (TAAT)

TAAT has the highest experimentally measured enthalpy of formation reported for any energetic organic compound measured up to this time (+2171 kJ/mol) [1255].

### 19.5 Multi-Substituted Triazines

2-Oxo-1,3,5-trinitro-1,3,5-triazine, K-6, 2-oxo-1,3,5-trinitro-1,3,5-triazacyclohexane, 1,3,5-trinitro-1,3,5-triazinan-2-one,  $C_3H_4N_6O_7$ ,  $M = 236.100$  g/mol, is a close relative of RDX. It has a density of  $1.932$  g/cm<sup>3</sup>, a DSC exotherm at 478 K (205 °C), and a measured explosive performance that is 4% greater than that of HMX [1256].

2-Oxo-1,3,5-trinitro-1,3,5-triazine

K-6 can be synthesized by reacting urea, formaldehyde, and *tert*-butyl amine to yield 5-*tert*-butyl-2-oxo-1,3,5-hexahydrotriazine. Nitrolysis of the *tert*-butyl group and further nitration gave K-6 in 21–57% yield, depending on the choice of the nitrolysis reagent. K-6 has superior hydrolytic stability compared to other cyclic dinitroureas, including tetranitroglycoluril (TNGU), K-55, and HK 55 [446]. Its properties are: m.p. = 469 K = 196 °C, impact sensitivity drop height 50% point at  $H_{50}$  = 61 cm, and its explosive performance is equivalent to that of HMX.

The multi-component reaction of 2,4,6-trichloro-1,3,5-triazine with potassium trinitromethanide and trinitroethanol was used for the synthesis of a hetaryl trinitroethyl ether, 2,4-bis(2,2,2-trinitroethoxy)-6-trinitromethyl-1,3,5-triazine, which was used as a precursor for the synthesis of substituted trinitroethoxytriazine by sequential nucleophilic substitution processes. This resulted in several trinitroethoxytriazines bearing a range of functional groups, including 2,4,6-tris-(2,2,2-trinitroethoxy)-1,3,5-triazine [1257].

Computations for 2,4,6-trinitro-1,3,5-triazine-1,3,5-trioxide (TNTATO) using molecular mechanics and DFT predicted the crystal structure, IR spectrum, electronic structure, thermodynamic properties, pyrolysis mechanism, thermal stability, gas-phase and condensed-phase HOFs, detonation performance, and burning rate of TNTATO [1258]. TNTATO has a symmetric hyperconjugation structure that contributes to its stability. TNTATO has a positive oxygen balance and can be used as an oxidizer.

## 19.6 Multi-Ringed Triazines

Instead of having only one triazine ring in the energetic molecule, it has also been attempted to link two triazine rings via an azo —N=N— or a hydrazo —NH—NH— linkage. The other method of connecting is to fuse two rings so they share two atoms along a side of the hexagon.

The syntheses of 4,4',6,6'-tetra(amino)hydrazo-1,3,5-triazine (**1**), tetra(hydroxyl-amino)-hydrazo-1,3,5-triazine (**2**), tetra(hydrazino)-hydrazo-1,3,5-triazine (**3**), and tetra(azido)hydrazo-1,3,5-triazine (**4**) are described in [1259]. Compound (**4**) was oxidized to 4,4',6,6'-tetra(azido)azo-1,3,5-triazine (**5**). The thermal and sensitivity properties of (**4**) and (**5**) were reported in addition to all physical properties of the new compounds. High-nitrogen compounds containing polyazides possess very high HOFs because their energy content rapidly increases with the number of energetic azido groups in the molecule. However, they are notorious for their extreme sensitivity to spark, friction, and impact as well as for their poor thermal stability. Therefore their applications are very limited. Examples include 3,6-diazido-1,2,4,5-tetrazine and cyanuric azide (2,4,6-triazido-1,3,5-triazine). 4,4',6,6'-tetra-(azido)hydrazo-1,3,5-triazine (TAHT) (**3**) and 4,4',6,6'-tetra(azido)azo-1,3,5-triazine (TAAT) (**4**) were synthesized and characterized by elemental analysis, XRD, DSC, HOF, and IR and NMR spectroscopy [1255, 1260]. Remarkably, the HOFs of these

polyazido compounds are much higher than those of polynitro and high-nitrogen compounds. The hydrazo and azo linkages not only desensitized the compounds but also dramatically increased the melting point of the polyazido products. The properties are summarized in Table 74.

**Table 74:** Properties of polyazido high-nitrogen triazine compounds.

| Compound                                            | Density           | DSC fast decomp. |     | Impact H50 (Type 12) | Friction (BAM) |                 | ESD spark |
|-----------------------------------------------------|-------------------|------------------|-----|----------------------|----------------|-----------------|-----------|
|                                                     | g/cm <sup>3</sup> | K                | °C  | cm                   | N              | kg <sub>f</sub> | J         |

Data source: [1244].

Fourteen simple triazines and 16 different azo —N=N— or hydrazo —NH—NH— linked symmetrical and unsymmetrical triazine derivatives with two triazine were synthesized and characterized [1231, 1261]. The substituents on the rings included chloro, amino, methoxy, hydrazino, and azido groups. When studying the thermal decomposition of the 16 compounds, the linkage between two triazine rings did not appear to alter the decomposition of substituents or act as a trigger mechanism for the decomposition of the triazine ring. Except for the azido-substituted triazine rings, the compounds studied had high thermal stability.

### 19.7 Other Triazine Derivatives

The oxygen balance of energetic triazine derivatives can be improved by not only attaching oxygen-containing groups like —NO<sub>2</sub> or forming salts with oxygen-containing anions, but also by incorporating oxygen in the ring or attaching it in a carbonyl group that is part of the ring; e.g., 2,4-diamino-1,3,5-triazine-6-one, 4,6-diamino-1*H*-1,3,5-triazin-2-one.

2,4-Diamino-1,3,5-triazine-6-one

Energetic salts (nitrate, perchlorate) prepared from 2,4-diamino-1,3,5-triazine-6-one, were synthesized and fully characterized by IR and NMR spectroscopy, elemental analysis, and DSC and had good thermal stability and low impact sensitivity [1262]. The density of the nitrate was  $1.691 \text{ g/cm}^3$  and the density of the perchlorate was  $1.854 \text{ g/cm}^3$ . Most of the salts decomposed at temperatures above 453 K (180 °C). The 2,4-diamino-1,3,5-triazine-6-one nitrate and 2,4-diamino-1,3,5-triazine-6-one perchlorate in particular decomposed at 576 K (303 °C) and 609 K (336) °C, respectively, and were fairly stable. Salts prepared from 2,4-diamino-1,3,5-triazine-6-one would have only a few advantages over salts prepared from melamine, with the latter being the more economical option.

Another way to increase the energy content of melamine-based triazines is to substitute one or two of the hydrogens on the amino groups with more energetic groups. An example is 2,4,6-tris(2,2,2-trinitroethylamino)-1,3,5-triazine. A simple route for the synthesis of 2,4,6-tris(2,2,2-trinitroethylamino)-1,3,5-triazine, N2,N4,N6-tris(2,2,2-trinitroethyl)-1,3,5-triazine-2,4,6-triamine, TTET,  $\text{C}_9\text{H}_9\text{N}_{15}\text{O}_{18}$ , CAS RN [384856-74-0],  $M = 615.258 \text{ g/mol}$ , has been developed [1263].

2,4,6-Tris(2,2,2-trinitroethylamino)-1,3,5-triazine (TTET)

The TTET compound was fully characterized by multi-nuclear ( $^1\text{H}$ ,  $^{13}\text{C}$ ) NMR and IR spectroscopy, elemental analysis, electron ionization mass spectrometry, and DSC. TTET was found to have good physical properties such as good thermal stability ( $T_{\text{dec}} = 459\text{ K} = 186^\circ\text{C}$ ), reasonable impact sensitivity (21.5 J), and high density ( $1.88\text{ g/cm}^3$ ). The detonation properties of TTET obtained with the empirical K-J equations identified it as a competitively energetic compound. Other compounds superior in predicted performance to RDX were 2-(3-nitro-1,2,4-oxadiazole)imino-5-nitro-hexahydro-1,3,5-triazine and 2-(3-nitro-1,2,4-oxadiazole)imino-5-nitroso-hexahydro-1,3,5-triazine [1264].

3,4,5-Triamino-1,2,4-triazolium (guanazinium) salts with promising energetic anions and the 6-nitroamino-2,4-diazido[1,3,5]triazinate anion (NADAT) were prepared and characterized by elemental analysis, IR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, and DSC [432]. The crystal structures of neutral NADAT were determined by single-crystal XRD. All the new salts exhibited desirable physical properties such as relatively high densities ( $1.63\text{--}1.78\text{ g/cm}^3$ ) and moderate thermal stabilities ( $T_{\text{dec}} = 482\text{--}530\text{ K} = 209\text{--}257^\circ\text{C}$ ) for 6-nitroamino-2,4-diazido-1,3,5-triazinate salts.

A collection of 110 energetic salts including many triazine derivatives were designed on paper (or the computer screen) using DFT methods to predict the enthalpies of formation, electronic structure, and energetic properties of a series of triazine-based ionic and non-ionic compounds [1265]. It was observed that the  $\text{--N}_3$  group, triazole, tetrazole, triazine, and tetrazine are effective structural units for increasing the  $\Delta H_f^\circ$ 's. The presence of the  $\text{--NO}_2$  and  $\text{--NHNO}_2$  groups in the same structure was found to help improve densities through strong inter- and intra-molecular hydrogen bonding. One of the theoretical molecules was the 2,4,6-trinitroamino-1,3,5-triazinate anion in the form of its ammonium or guanidinium salt. The predicted explosive performance indicated that most of the compounds would outperform RDX and TATB.

A new class of nitroguanidyl-functionalized nitrogen-rich materials derived from 1,3,5-triazine and 1,2,4,5-tetrazine was synthesized through reactions between *N*-nitroso-*N'*-alkylguanidines and the hydrazine derivatives of 1,3,5-triazine or 1,2,4,5-tetrazine [1266]. These compounds were characterized using NMR and IR spectroscopies, elemental analysis, and DSC. The HOFs for all compounds were calculated and then combined with experimental densities to determine the detonation pressures and detonation velocities. For some of the compounds, the predicted explosive performances were comparable to that of RDX. Another energetic nitroimine compound is dinitroammeline, 4,6-bis(nitroimino)-1,3,5-triazinan-2-one [1267].

### 19.7.1 Cyanuric Acid

Cyanuric acid, also known as 1,3,5-triazine-2,4,6-triol, 1,3,5-trihydroxytriazine,  $C_3H_3N_3O_3$ , CAS RN [108-80-5], can serve as the anion for several energetic salts. Ammonium, hydrazinium, aminoguanidinium, diaminoguanidinium, triaminoguanidinium, aminonitroguanidinium, aminocarbonylguanidinium, and dimethylbiguanidinium cyanurates were synthesized by metathetical reactions. The crystal structures of a few were determined by single-crystal XRD and further characterized by UV-vis, FTIR,  $^1H$  NMR, MS, and elemental analysis [1268]. DTA and TGA results showed that all compounds had high thermal stabilities. Impact sensitivities determined by the fall hammer test showed impact sensitivities of  $>60$  J, which are less sensitive than that of TATB (50 J).

## 19.8 Fused-Ring Triazines

A fused-ring conjugated energetic molecule, 4-amino-3,7-dinitro-[1,2,4]triazolo[1,5-c][1,2,4]triazine, also known as 3,7-dinitro-[1,2,4]triazolo[1,5-c][1,2,4]triazin-4-amine,  $C_4H_2N_8O_4$ , TTX,  $M = 226.11$  g/mol, has been synthesized in a two-step process, starting from the known 5-amino-3-nitro-1*H*-1,2,4-triazole (ANTA) [1269].

4-Amino-3,7-dinitro-[1,2,4]triazolo[5,1-c][1,2,4]triazine (TTX)

Characterization of TTX showed that it possesses energetic properties approaching those of 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX) but with a higher thermal stability and lower sensitivity towards impact and friction. TTX crystalized as monoclinic crystals, space group *Cc* with three molecules in the asymmetric unit with a calculated crystal density of  $\rho = 1.86$  g/cm<sup>3</sup> at 150 K. TTX is highly stable thermally ( $T_{dec} = 545$  K = 272°C) and has a pycnometric density of  $\rho = 1.82$  g/cm<sup>3</sup>. Both of these important parameters of TTX exceed those of RDX ( $T_{dec} = 477$  K = 204°C;  $\rho = 1.80$  g/cm<sup>3</sup>). The HOF was calculated to be +403.5 kJ/mol = 1.78 kJ/g.

A triazolotriazine carbonitrile (**1**) was formed by diazotization of 3-amino-5-cyano-1,2,4-triazole followed by treatment with nitroacetonitrile [1270]. Cyclization of the nitrile  $C\equiv N$  bond with sodium azide results in 3-nitro-7-(1*H*-tetrazol-5-yl)-[1,2,4]triazolo[1,5-c][1,2,4]triazin-4-amine (**2**).

Compounds **(1)** and **(2)** were characterized by elemental analysis, IR spectroscopy,  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopy, and single-crystal XRD. Compound **(2)** has a density of  $\rho = 1.819 \text{ g/cm}^3$ , is thermally stable up to 578 K (305 °C), and is insensitive to impact, friction, or electrical discharge. The enthalpy of formation ( $\Delta H_f$ ) values for **(1)** and **(2)** were calculated and found to be 533 and 753 kJ/mol (127.5 and 179.9 kcal/mol), respectively. The detonation pressure and velocity of **(2)** were calculated to be 27.04 GPa and 8.312 km/s, respectively, making this a good 1,3,5-triamino-2,4,6-trinitrobenzene (TATB) replacement candidate.

#### 19.8.1 1,3,5-Trioxa-2,4,6-triazine

A purely speculative compound that has never been synthesized but would make a good rocket propellant is 1,3,5-trioxa-2,4,6-triazine, 1,3,5,2,4,6-trioxatriazinane,  $\text{H}_3\text{N}_3\text{O}_3$  (note that there is no carbon in this heterocyclic compound).

1,3,5-Trioxa-2,4,6-triazine

The enthalpies of formation of the gas-phase species were computed according to the atomization energy method and found to be  $\Delta H_f^\circ(\text{G}) = +100.6 \text{ kcal/mol}$  [1271]. The enthalpy of sublimation for  $\text{H}_3\text{N}_3\text{O}_3$  was estimated as 74 kJ/mol = 17.7 kcal/mol according to Trouton's rule. With the estimated sublimation enthalpy, the enthalpy of forma-

tion for solid 1,3,5-trioxa-2,4,6-triazine was calculated to be  $\Delta H_f^\circ(\text{S}) = +347 \text{ kJ/mol} = +82.9 \text{ kcal/mol}$ . The density of  $\text{H}_3\text{N}_3\text{O}_3$  was calculated to be  $\rho = 1.60 \text{ g/cm}^3$  from the molecular volume.

## 19.9 Azotriazines

Preliminary information on azotriazines and hydrazotriazines was presented in the section on azidotriazines and detailed further in Table 74. Additional information is provided here.

4,4',6,6'-Tetra(azido)azo-1,3,5-triazine,  $\text{C}_6\text{N}_{20}$ , TAAT,  $M = 352.21 \text{ g/mol}$  with 79% N and 4,4',6,6'-tetra(azido)hydrazo-1,3,5-triazine (TAHT) and a set of computer-designed bridged triazines with similar bridges were studied theoretically to facilitate further laboratory developments [1272]. The molecular structure of TAAT has already been detailed in an earlier section of this chapter.

The gas-phase enthalpies of formation of TAAT and TAHT were predicted based on isodesmic reactions by using a DFT method. The estimates of the condensed-phase enthalpies of formation and heats of sublimation were estimated in the framework of the Politzer approach. Calculations showed that the method provided a good estimation for enthalpies in comparison with available experimental data for TAAT and TAHT. The crystal density was computed using molecular packing calculations. The calculated detonation velocities and detonation pressures indicated that  $-\text{NF}_2$ ,  $-\text{NO}_2$ ,  $-\text{N}=\text{N}-$ , and  $-\text{N}=\text{N}(\text{O})-$  groups would be effective structural units for improving the detonation performance of bridged triazines. The synthesized TAAT and TAHT were not preferred energetic materials due to their inferior detonation performance. The  $p \rightarrow \pi$  conjugation effect between the triazine rings and bridges makes the molecules more stable as a whole. An analysis of the BDE showed that these derivatives had good thermal stability over RDX and HMX, and the  $-\text{NH}-\text{NH}-$  bridge is more helpful for improving the stability than  $-\text{N}=\text{N}(\text{O})-$  and  $-\text{N}=\text{N}-$  bridges.

The enthalpies of formation, electronic structures, energetic properties, and thermal stabilities of a series of bridged 1,3,5-triazine derivatives with different substituents and linkages were studied using DFT methods [1273]. Azido groups and  $-\text{N}=\text{N}-$  azo bridges are effective structural units for improving the  $\Delta H_f$  values of di-1,3,5-triazine derivatives. The  $-\text{NH}_2$ ,  $-\text{N}_3$ ,  $-\text{NH}-$ , and  $-\text{CH}=\text{CH}-$  groups are effective structural units for increasing the thermal stabilities of the derivatives. Based on detonation performance and thermal stability, nine of the compounds are promising candidates for HEDMs with reduced sensitivity.

A detailed study on the structural, electronic, and thermodynamic properties of the solid polyazide 4,4',6,6'-tetra(azido)azo-1,3,5-triazine (TAAT) under the hydrostatic pressure of 0-100 GPa was performed using a DFT computational method [1274]. The predicted crystal structure compared well with experimental results at

ambient pressure. The results showed that a pressure less than 40 GPa does not significantly change the crystal and molecular structures. When higher pressure is applied, the molecular geometry, band structure, and density of states change except at 48 and 90 GPa where the azide-tetrazole transformation occurs. At 48 GPa, the tetrazole rings are almost coplanar with the triazine rings, whereas it has a big deviation at 90 GPa. The azide cyclization for polyazido-1,3,5-triazine has not been observed in the gas phase or in polar solvents. An analysis of the density of states showed that the electronic delocalization in TAAT increases generally under the influence of pressure. This indicates that an applied pressure may increase the impact sensitivity.

### 19.10 Hydrazotriazines

DFT calculations were performed to study hydrostatic compression effects on the structure, electronic, and thermodynamic properties of 4,4',6,6'-tetraazido-hydrazo-1,3,5-triazine (TAHT) in the range of 0–100 GPa [1275]. At ambient pressure, the relaxed crystal structure compared well with experimental results. The predicted heat of sublimation was 161.8 kJ/mol (38.68 kcal/mol), and the evaluated condensed phase enthalpy of formation ( $\Delta H_f = +1732$  kJ/mol = +414.04 kcal/mol) approximated the experimental value. The detonation velocity and detonation pressure for solid TAHT were predicted to be 7.44 km/s and 23.71 GPa, respectively. When examining the effect of pressure on molecular structure, at less than 35 GPa, the crystal structure and geometric parameters changed only slightly. However, at 36 GPa, the molecular structure, band structure, and density of states changed abnormally because of the azide-tetrazole transformation. This has not been observed in the gas phase or in polar solvents. The azido group cyclizes to form a five-membered tetrazole ring that is coplanar with the triazine ring and contributes to a larger conjunction system. An analysis of the electronic structure showed that an applied pressure would increase the impact sensitivity of TAHT.

### 19.11 Heptazine
